ABSTRACT OF THE THESIS

Probing mSUGRA with a Search for Chargino-Neutralino Production using Trileptons

by Julian Glatzer

Thesis Director: Prof. Sunil Somalwar

This thesis describes the CDF II 2 fb^{-1} search for supersymmetric chargino-neutralino production in $\sqrt{s} = 1.96\text{ TeV}$ $p\bar{p}$ collisions using the “golden” channel with three leptons and missing transverse energy in the final state and the application of the results to obtain a limit on the parameter space of the supersymmetric model mSUGRA.

Electrons and muons are reconstructed directly; isolated tracks are used as a proxy for τ leptons. Several analysis channels with different signal purity are defined and evaluated independently. Based on 7 observed and 6.4 expected background events this analysis was able to set the first direct limits on chargino-neutralino production in mSUGRA since LEP. Based on mSUGRA phenomenology the sensitivity of this analysis is investigated; the mSUGRA parameter space is split into different phenomenology classes.

Experimental results from previous searches in this channel by CDF and DØ have been presented for specific parameter values of a given model. A more model-independent approach is proposed and, by splitting the results of this analysis into channels based on τ content, the results of the analysis are generalized.

Acknowledgements

I want to express my deep gratitude to my advisor Prof. Sunil Somalwar. Thank you for supporting me at any time and keeping a clear overview whenever I feared to lose it. I have enjoyed the time as your student very much and have learnt from you far more than physics. I am much obliged to Sourabh Dube for being my supreme guide into high energy physics. This thesis would not have been possible in this way without your work and help. I also want to thank Alexander Sood for always being here, when help was needed, Prof. Scott Thomas for important help with all theory-related questions and numerous easily comprehensible explanations, Prof. Amitabh Lath, Prof. Eva Halkiadakis, Daryl Hare, Prof. Matthew Strassler and the whole high energy experiment group for a great time. At CDF I want to thank Prof. Benjamin Brau, Prof. Christopher Hays, Dr. Monica D’Onofrio and Prof. David Toback for their support and the pleasant environment in the CDF Exotic and SUSY working group. I want to thank the “Amerika-Programm” of the University of Würzburg and Rutgers University, especially Prof. Ronald Ransome, Shirley Hinds, Prof. Fakher Assaad and the Deutscher Akademischer Austauschdienst for making my stay at Rutgers University possible.

Friends are what make life worth living. Carolin, thanks for giving me all the compliments I don’t deserve, but make me feel great. Jenny, thanks for even joining me in the most senseless talks and understanding all my kidding. Martin, thanks for being a great person to talk to about even the most absurd topics. Rebecca, thanks that I have always been able to count on you. Silvia, thanks for being the only person in this world who appreciates my taste of music and for always being a great source of welcome distraction. I also want to thank Achim, Andrea, Johannes, Florian, Gencho, Mario, Miriam, Nina, Oliver, Sebastian, Sonja, Tim and all other people, which are missing in this list, for spending all these nice days and evenings with me and making my time in Würzburg so incredible. Thank you, Niki, for keeping an old and valued friendship alive even though we can’t meet regularly.

I also want to thank Robert and Jean-Patrick for sharing a lot of nice moments with me during my time at Rutgers.

Thank you, Corinne, for being with me for such a long time and knowing me like no one else does. Thank you for all your support, for the freedom I got from you and for bearing the side-effects when I am determined to achieve something. I want to thank my family, Benedikt, Christine and Manfred, for supporting me and being able to judge what is important in life — and what is not. I thank you for being the people you are, open-minded and supporting what is worth working and fighting for, but at the same time giving me freedom when I need it. Vielen Dank.

Dedication

To life and all the liberal and open-minded people who make it so enjoyable.

Chapter 1

Introduction

“There’s Plenty of Room at the Bottom”¹

Richard P. Feynman

The universe, stars, planets, oceans, mountains, trees and humans, everything around us is made of matter. The question, what the universe and all matter is made of and if there is a smallest constituent, that makes up all matter, is one of the oldest questions that has been asked by humanity. The idea that the universe is made of small and simple building blocks is old and has probably first come up in the 6th century BC in ancient India, even though the idea is now often ascribed to Democritus. To search at a very small distance scale very high energies are necessary. In high energy physics experiments particles such as electrons or protons are accelerated to nearly the speed of light. In a collision of two particles, very high energy densities, similar to the ones that existed right after the Big Bang, are created and smaller structures, that might make up our matter, can be revealed.

What is mass? What is dark matter? Are there any other fundamental particles we have not yet seen? Are all forces low-energy realizations of a single force at a higher energy? Particle physics might be able to find first answers to these questions in the next years. The Tevatron at Fermilab near Chicago and the Large Hadron Collider at CERN near Geneva are two particle physics experiments that can accelerate protons to energies where secondary particle can be produced that no other experiment was ever able to see. The Higgs boson might give an answer to how particles acquire mass and supersymmetry — if realized in nature — doubles the number of elementary particles and might explain the nature of dark

¹“There’s Plenty of Room at the Bottom” is the title of a talk given by Richard P. Feynman. Even though Feynman’s talk was on the topic of nanophysics the idea is also applicable at the even smaller scale of particle physics.

matter. Supersymmetry might be the next step towards a deeper understanding of the fundamental symmetries and laws of nature.

This thesis will document a search for supersymmetry at the Collider Detector at Fermilab (CDF II). At the Tevatron protons collide with antiprotons at a center-of-mass energy of 1.96 TeV and a pair of supersymmetric particles, the chargino and the neutralino, may be produced. They may subsequently decay into three leptons along with weakly interacting particles, that can be seen in the detector as missing transverse energy. The Standard Model of Particle Physics is currently the best and very successful description of most experimental observations in high energy physics. As the Standard Model predicts a low number of events with three leptons and missing transverse energy in the final state, this signature is a good experimental probe to discover deviations from the Standard Model. Even though the signature with which this search is carried out is tailored towards a special realization of supersymmetry, it is possible to see deviations from the Standard Model due to other models.

A Note on Units and used Terminology

In particle physics it is commonly accepted to use units where $\hbar = c = 1$. In this thesis units are determined up to powers of \hbar and c ; however in special cases powers of \hbar and c are given.

The term neutralino will be used for the next-to-lightest neutralino $\tilde{\chi}_2^0$; by chargino we denote the lighter chargino $\tilde{\chi}_1^\pm$ and by LSP² the lightest neutralino $\tilde{\chi}_1^0$. The term lepton will be used context-dependent and includes electrons and muons or electrons, muons and τ leptons or electrons, muons, τ leptons and the matching neutrinos.

²LSP is an abbreviation for lightest supersymmetric particle. In the parameter space considered in this analysis the lightest neutralino is the lightest supersymmetric particle.

Chapter 2

Overview and Theoretical Background

2.1 The Standard Model of Particle Physics

The Standard Model of Particle Physics (SM) describes the electromagnetic, the weak and the strong interaction between the elementary particles of which all matter consists. It is formulated as a relativistic quantum field theory using the gauge group

$$U(1)_Y \times SU(2)_L \times SU(3)_C \quad (2.1)$$

as an abstract description of the interactions. The basis of the Standard Model of Particle Physics was developed in the first half of the 1970's and confirmed in numerous experimental probes.

2.1.1 Elementary Particles

The elementary particles in the Standard Model of Particle Physics can be divided into bosons and fermions. Bosons have integer spin ($J \in \{0, 1, 2, 3, \dots\}$) and act as the carriers of the four fundamental forces of nature, whereas fermions are particles with half-integer spin ($J \in \{\frac{1}{2}, \frac{3}{2}, \frac{5}{2}, \dots\}$). The interactions of fermions are described by gauge theories and are mediated by the exchange of gauge bosons.

Elementary Fermions

The elementary particles our normal matter is made of are fermions. Examples for these particles are electrons and the up and down quark of which the proton and neutron are made. Elementary fermions have spin $J = \frac{1}{2}$.

Elementary fermions can be categorized into quarks, which can participate in the strong, the weak and the electromagnetic interaction, and leptons, which can participate in the weak

and the electromagnetic interaction only. The elementary fermions can be ordered in three generations, where in the first generation up and down quark as well as electron and electron neutrino are, in the second generation charm and strange quark as well as muon and muon neutrino and in the third generation bottom and top quark as well as tau and tau neutrino. A schematic ordering of these particles can be found in Table 2.1.

Quarks (antiquarks) carry a baryon quantum number of $B = 1/3$ ($B = -1/3$), which is approximately conserved even though a violation has not yet been observed. A quark-antiquark pair can form a meson ($B = 0$) and three quarks can form a baryon ($B = \pm 1$). Other combinations of quarks have not yet been observed. Protons, made of two up and one down quark, and neutrons, made of one up and two down quarks, are baryons. As quarks are spin $1/2$ particles they can occur in a left- and right-handed form according to the orientation of their spin. The right-handed quarks form weak-isospin singlets, the left-handed quarks of one generation form a weak-isospin doublet.

Leptons (antileptons) carry a lepton quantum number of $L = 1$ ($L = -1$), which is approximately conserved even though a violation has not yet been observed¹. The difference of baryon and lepton quantum number $B - L$ is absolutely conserved. The left-handed leptons and the neutrino of the same flavor form a weak-isospin doublet. The right-handed lepton forms a weak-isospin singlet. In the Standard Model there is no right-handed neutrino, however newer experiments suggest non-vanishing neutrino masses, which might be a reason for a right-handed neutrino to exist.

Elementary Gauge Bosons

The gauge bosons that are included in the Standard Model of Particle Physics are the photon γ , which is mediating the electromagnetic interaction, the W^+, W^-, Z^0 bosons, which are mediating the weak force, and the gluon g , which is mediating the strong color force. The hypothetical graviton G , which might be mediating gravity is not included in the Standard Model. An overview of the properties of the elementary gauge bosons can be found in Table 2.2.

¹A violation of the lepton family numbers has been observed in the process of neutrino oscillations.

Table 2.1: The elementary fermions and their masses^a

generation	quarks ^b		leptons	
1	$\begin{pmatrix} u \\ d' \end{pmatrix}_L, u_R, d_R$		$\begin{pmatrix} e \\ \nu_e \end{pmatrix}_L, e_R$	
	up	down	electron	electron neutrino
mass · c ²	1.5 to 4 MeV	3 to 7 MeV	511 keV	< 460 eV
2	$\begin{pmatrix} c \\ s' \end{pmatrix}_L, c_R, s_R$		$\begin{pmatrix} \mu \\ \nu_\mu \end{pmatrix}_L, \mu_R$	
	charm	strange	muon	muon neutrino
mass · c ²	1.25 GeV	95 MeV	105.7 MeV	< 190 keV
3	$\begin{pmatrix} t \\ b' \end{pmatrix}_L, t_R, b_R$		$\begin{pmatrix} \tau \\ \nu_\tau \end{pmatrix}_L, \tau_R$	
	top	bottom	tau lepton	tau neutrino
mass · c ²	172.3 GeV	4.20 GeV	1.777 GeV	< 18.2 MeV

^aAntiparticles are not listed. Masses are according to [1].^bThe down-type quarks appearing in the doublets d' , s' and b' are interaction eigenstates. Mass eigenstates are obtained by diagonalizing the Cabibbo-Kobayashi-Maskawa matrix[2].

The Standard Model Lagrangian is built of kinetic terms of the form

$$\mathcal{L} = \bar{\Psi} \not{D} \Psi, \quad (2.2)$$

where Ψ is a Dirac spinor, for all fermions and terms for the potential energy and interactions. The gauge bosons enter the Lagrangian in the definition of

$$\not{D} = \gamma^\mu D_\mu, \quad D_\mu = \partial_\mu - \frac{i}{2} g_2 W_\mu^a \sigma^a - i g_Y Y_\phi B_\mu, \quad (2.3)$$

where the fields W_μ and B_μ mix to form the W^+, W^-, Z^0 bosons and the photon, γ^μ are the Dirac and σ^a the Pauli matrices; g_2 and g_Y are the coupling parameters for the $U(1)$ electromagnetic and the $SU(2)$ weak interaction. A more complete description of the Standard Model Lagrangian and the syntax used here can be found in [3].

The Higgs Boson

The Higgs boson is a hypothetical particle that can explain the origin of mass. In its minimal Standard Model version it is represented by a scalar field $\phi = (\phi_1, \phi_2)^T$ and yields the Lagrangian contribution[4]

$$\mathcal{L}_\phi = (D_\mu \phi)^\dagger D_\mu \phi - \mu^2 \phi^\dagger \phi - \lambda (\phi^\dagger \phi)^2. \quad (2.4)$$

The gauge symmetry of the Lagrangian is broken when a specific vacuum expectation value is chosen to minimize the potential:

$$\langle \phi \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix}, \quad \text{where } v = \sqrt{\frac{-\mu^2}{\lambda}} \quad \mu^2 < 0, \lambda > 0. \quad (2.5)$$

The term $(D_\mu \phi_i)^2$ now includes the term

$$\underbrace{\frac{1}{4} g_2^2 (\sigma^a \phi)_i (\sigma^b \phi)_i}_{=m_{ab}^2 \text{ for } \phi=\phi_0} A_\mu^a A^{\mu b}, \quad (2.6)$$

where m_{ab}^2 , after diagonalization, results in the boson masses

$$m_W^2 = \frac{1}{4} g_2^2 v^2, \quad m_Z^2 = \frac{1}{4} (g_2^2 + g_Y^2) v^2. \quad (2.7)$$

Fermion masses result from a Yukawa coupling to the Higgs boson doublet.

Table 2.2: The four fundamental forces and their mediating gauge bosons^a[5].

Force	Gravity ^b	Electromagnetic Force	Weak Force	Strong Force
Field Boson	Graviton G	Photon γ	W^\pm, Z^0	Gluon g
Spin-Parity	2^+	1^-	$1^-, 1^+$	1^+
Mass	0	0	80.4 GeV (W), 91.2 GeV (Z)	0
range	∞	∞	$\sim 10^{-18}$ m	$\lesssim 10^{-15}$ m
source	mass	electric charge	‘weak charge’	‘color charge’
coupling constant (effective)	$\frac{G_N M^2}{4\pi\hbar c}$ $\approx 5 \cdot 10^{-40}$	$\alpha = \frac{e^2}{4\pi\hbar c}$ $\approx \frac{1}{137}$	$\frac{G(Mc^2)^2}{(\hbar c)^3}$ $\approx 1.17 \cdot 10^{-5}$	$\alpha_s \leq 1$
potential	$\propto \frac{1}{r}$	$\propto \frac{1}{r}$	$\propto \frac{\exp -m_{W,Z}r}{r}$	$\propto Kr - \frac{\alpha}{r}$

^aNumbers are calculated for for $Mc^2 = 1$ GeV.

^bGravity is not included in the Standard Model of Particle Physics; the graviton is a hypothetical particle.

2.1.2 Fundamental Interactions

As of now the four known fundamental forces are: the strong force, the weak force, the electromagnetic force and gravity. Except for gravity, all fundamental interactions can be described within the framework of the Standard Model of Particle Physics. The electromagnetic force and the weak force can be described by the electroweak theory which is a unified theory of quantum electrodynamics and the weak interaction. The strong force can be described by quantum chromodynamics. As long as energies are well below the Planck scale M_P effects of gravity can be neglected², but the fact that the Standard Model of Particle Physics has to break down at energies comparable to the Planck scale can be taken as a hint that the Standard Model is an effective theory for energies smaller than the Planck scale.

²It is $M_P = \sqrt{\frac{\hbar c}{G_N}} \approx 1.22 \cdot 10^{28}$ eV.

2.2 Supersymmetry

Supersymmetry is a proposed symmetry, which relates bosons and fermions. The supersymmetry operator Q_r acts on bosons (fermions) according to

$$Q_r |\text{boson}\rangle = |\text{fermion}\rangle \quad Q_r |\text{fermion}\rangle = |\text{boson}\rangle \quad (2.8)$$

and introduces a superpartner for every Standard Model particle. The superpartner differs from the Standard Model particle by spin $\frac{1}{2}$, so that the superpartner for a boson is a fermion and the superpartner for a fermion is a boson.

2.2.1 Particles of the Minimal Supersymmetric Standard Model

The Minimal Supersymmetric Standard Model (MSSM) tries to parameterize a model with minimal particle content and soft supersymmetry breaking in a way as general as possible. In the flavor sector alone it has 110 free parameters: 30 masses, 39 real mixing angles and 41 phases[6].

While in the Standard Model one scalar Higgs boson is enough to generate masses, in the Minimal Supersymmetric Standard Model two Higgs doublets

$$H_u = \begin{pmatrix} H_u^+ \\ H_u^0 \end{pmatrix}, \quad H_d = \begin{pmatrix} H_d^0 \\ H_d^- \end{pmatrix} \quad (2.9)$$

are needed. The vacuum expectation values of the two Higgs doublets are related to the Standard Model Z boson mass and the couplings g_2 and g_Y via Eqn. 2.7, so that

$$\langle H_u \rangle^2 + \langle H_d \rangle^2 = v_u^2 + v_d^2 = v^2 = \frac{2m_Z^2}{g_Y^2 + g_2^2} = \frac{2m_W^2}{g_2^2} \approx (174 \text{ GeV})^2 [7]. \quad (2.10)$$

The ratio of the vacuum expectation values of the two Higgs doublets

$$\tan \beta = \frac{v_u}{v_d} \quad (2.11)$$

is a free parameter of the theory. As all components of the two doublets can be complex, eight degrees of freedom exist[8] and mix to form the five physical states of the Higgs

spectrum H^\pm , A^0 , h^0 , H^0 and the three Goldstone bosons, that provide the longitudinal components of the massive W^\pm and Z^0 bosons via the Higgs mechanism. It is

$$H^\pm = H_d^\pm \sin \beta + H_u^\pm \cos \beta, \quad (2.12)$$

$$A^0 = \sqrt{2} (\text{Im} H_d^0 \sin \beta + \text{Im} H_u^0 \cos \beta), \quad (2.13)$$

$$h^0 = - \left(\sqrt{2} \text{Re} H_d^0 - v_d \right) \sin \alpha + \left(\sqrt{2} \text{Re} H_u^0 - v_u \right) \cos \alpha, \quad (2.14)$$

$$H^0 = \left(\sqrt{2} \text{Re} H_d^0 - v_d \right) \cos \alpha + \left(\sqrt{2} \text{Re} H_u^0 - v_u \right) \sin \alpha. \quad (2.15)$$

The superpartners of the Higgs bosons are the Higgsinos. In a superfield formulation usual mass terms for the Higgs superfields H_u , H_d can not be introduced as the superpotential has to be analytic in the superfields. In the supersymmetric Lagrangian the term

$$\mu H_u H_d, \quad (2.16)$$

where μ is the Higgs mixing parameter, is introduced to ensure electroweak symmetry breaking[9] and give mass to all quarks and leptons. Together with the Bino \tilde{B}^0 and the neutral Wino \tilde{W}^0 the neutral Higgsinos \tilde{H}_d^0 and \tilde{H}_u^0 form mass eigenstates, the so-called neutralinos $\tilde{\chi}_i^0$, $i = 1, 2, 3, 4$. The charged Higgsinos \tilde{H}^\pm together with the charged Winos \tilde{W}^\pm also mix and form mass eigenstates, the charginos $\tilde{\chi}_i^\pm$, $i = 1, 2$.

In the Standard Model six doublets, containing the three generations of left-handed leptons and quarks $(e_i, \nu_i)_L$, $(u_i, d_i)_L$, and nine singlets, containing the right-handed leptons and quarks $e_{i,R}$, $u_{i,R}$, $d_{i,R}$, exist. According to section 2.2 for every Standard Model doublet a supersymmetric doublet and for every Standard Model singlet a supersymmetric singlet exists, containing the selectrons, smuons, stau sleptons and squarks

$$(\tilde{e}, \tilde{\nu}_e)_L, (\tilde{\mu}, \tilde{\nu}_\mu)_L, (\tilde{\tau}, \tilde{\nu}_\tau)_L, \tilde{e}_R, \tilde{\mu}_R, \tilde{\tau}_R \quad (2.17)$$

$$(\tilde{u}, \tilde{d})_L, (\tilde{c}, \tilde{s})_L, (\tilde{t}, \tilde{b})_L, \tilde{u}_R, \tilde{d}_R, \tilde{c}_R, \tilde{s}_R, \tilde{t}_R, \tilde{b}_R. \quad (2.18)$$

The superpotential of the MSSM is[7]

$$W_{\text{MSSM}} = \bar{u}_R \mathbf{y}_u Q_L H_u - \bar{d}_R \mathbf{y}_d Q_L H_d - \bar{e}_R \mathbf{y}_e L_L H_d + \mu H_u H_d, \quad (2.19)$$

where H_u , H_d , Q_L , L_L , \bar{u}_R , \bar{d}_R , \bar{e}_R are chiral superfields and L, R denotes left- and right-handed particle content. \mathbf{y}_u , \mathbf{y}_d , \mathbf{y}_e are the Yukawa matrices and in the approximation that

$$\mathbf{y}_u \approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & y_t \end{pmatrix}, \mathbf{y}_d \approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & y_b \end{pmatrix}, \mathbf{y}_\tau \approx \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & y_\tau \end{pmatrix} \quad (2.20)$$

the superpotential is

$$W_{\text{MSSM}} \approx y_t(\bar{t}tH_u^0 - \bar{t}bH_u^+) - y_b(\bar{b}tH_d^- - \bar{b}bH_d^0) - y_\tau(\bar{\tau}\nu_\tau H_d^- - \bar{\tau}\tau H_d^0) + \mu(H_u^+ H_d^- - H_u^0 H_d^0). \quad (2.21)$$

In this approximation it can be seen that the third generation superfields have a coupling to the Higgs superfields while the first and second generation superfields do not. The consequence of this approximation is that the first and second generation gauge and mass eigenstates are approximately equal while left- and right-handed sfermions of the third generation mix to form the sfermions

$$\tilde{\tau}_1, \tilde{\tau}_2, \tilde{\nu}_\tau, \tilde{t}_1, \tilde{t}_2, \tilde{b}_1, \tilde{b}_2. \quad (2.22)$$

According to [7], the degree of mixing depends on the ratio of the vacuum expectation values of the two Higgs doublets $\tan\beta$. For moderate $\tan\beta$ the mass eigenstates are similar to the gauge eigenstates³.

2.2.2 R-Parity

R-parity is a possible symmetry of the supersymmetric Lagrangian. It was first introduced to suppress lepton and baryon number violating processes at low energy scale and is defined by

$$R = (-1)^{3B+L+2s}, \quad (2.23)$$

where B is the baryon number, L is the lepton number and s is the spin⁴. It can be seen that this combination ensures that

³In practice moderate $\tan\beta$ means $\tan\beta < 10$.

⁴As B, L, s are quantized the definition $R = (-1)^{3(B-L)+2s}$ is equivalent.

- $R = 1$ for Standard Model particles
- $R = -1$ for supersymmetric particles.

For this thesis it is assumed that — if supersymmetry is realized in nature — R-parity violating interaction vertices are not allowed and thus that R-parity is conserved. This has important consequences for the experimental signatures that can possibly be seen in detectors, as interactions always have to happen with an even number of supersymmetric particles and the lightest supersymmetric particle (LSP) is not able to decay and thus provides a good candidate for non-baryonic dark matter, if it is neither electrically nor color charged. As the LSP has $R = -1$ it can neither decay to supersymmetric particles, as this would violate energy conservation, nor to Standard Model particles, as this would violate R-parity conservation. If the lightest supersymmetric particle would have had electric or color charge it would be bound to nuclei and nuclei with unusual charge to mass ratio have not been observed[10]. The LSP escapes particle detectors unseen and carries away momentum. In hadron colliders the transverse momentum is conserved and a momentum imbalance can be a hint for a particle that was not seen in the detector. Momentum imbalance is an important signature for possibly supersymmetric events provided R-parity is conserved.

2.2.3 Supersymmetry Breaking

One of the axioms of the supersymmetry algebra[11] is

$$[Q_r, P^\mu] = 0, \quad (2.24)$$

where Q_r is the supersymmetry operator and P^μ the four-momentum operator. Let $|\text{boson}\rangle$ and $|\text{fermion}\rangle$ be a Standard Model particle and its superpartner, so that $Q_r |\text{boson}\rangle = |\text{fermion}\rangle$. It is thus

$$P^\mu P_\mu Q_r |\text{boson}\rangle = P^\mu P_\mu |\text{fermion}\rangle = m_f^2 |\text{fermion}\rangle \quad (2.25)$$

$$= Q_r P^\mu P_\mu |\text{boson}\rangle = m_b^2 |\text{fermion}\rangle, \quad (2.26)$$

where m_b and m_f are the masses of the boson and fermion respectively. If supersymmetry is not broken, it follows that $m_f = m_b$. The searches of collider experiments, however, have

not found particles that are consistent with superpartners, so that — if supersymmetry is realized in nature — it has to be broken.

For phenomenological reasons, the supersymmetry breaking term should be soft enough to avoid reintroducing the hierarchy problem or destroying the unification of forces which is a good motivation for supersymmetry⁵. Without an underlying breaking model the most general supersymmetry breaking terms that assure these conditions are[7]

$$\begin{aligned}
\mathcal{L}_{\text{soft}}^{\text{MSSM}} = & -\frac{1}{2} \left(M_1 \tilde{B} \tilde{B} + M_2 \tilde{W} \tilde{W} + M_3 \tilde{g} \tilde{g} + \text{c.c.} \right) \\
& - \left(\tilde{u}_R \mathbf{a}_u \tilde{Q}_L H_u - \tilde{d}_R \mathbf{a}_d \tilde{Q}_L H_d - \tilde{e}_R \mathbf{a}_e \tilde{L}_L H_d + \text{c.c.} \right) \\
& - \tilde{Q}_L^\dagger \mathbf{m}_Q^2 \tilde{Q}_L - \tilde{L}_L^\dagger \mathbf{m}_L^2 \tilde{L}_L - \tilde{u}_R \mathbf{m}_u^2 \tilde{u}_R^\dagger - \tilde{d}_R \mathbf{m}_d^2 \tilde{d}_R^\dagger - \tilde{e}_R \mathbf{m}_e^2 \tilde{e}_R^\dagger \\
& - m_{H_u}^2 H_u^* H_u - m_{H_d}^2 H_d^* H_d - (b H_u H_d + \text{c.c.}) ,
\end{aligned} \tag{2.27}$$

where M_i , $i = 1, 2, 3$ are the mass terms for Bino, Wino and gluino; \mathbf{a}_i are the scalar trilinear couplings; m_i^2 , $i = L, Q, \bar{u}, \bar{d}, \bar{e}$ the slepton and squark mass terms and $m_{H_u}^2$, $m_{H_d}^2$ and b the Higgs mass and mixing terms.

The way supersymmetry is broken affects the phenomenology of the specific supersymmetric model and most supersymmetric models are named after the breaking mechanism, e.g.

- gravity mediated supersymmetry breaking
- gauge mediated supersymmetry breaking.

Many theories of supersymmetry have at least two sectors: A visible sector, consisting of the supersymmetric particles which have been introduced earlier, and a hidden sector, consisting of particles which have no or very weak direct tree-level interactions with particles from the visible sector. Supersymmetry breaking is usually assumed to occur in the hidden sector and is transferred to the visible sector. Often this involves a third so-called messenger sector. The supersymmetry breaking mediated by gravity happens at the Planck scale

$$M_P = \sqrt{\frac{\hbar c}{G_N}} \approx 1.22 \cdot 10^{28} \text{ eV} \tag{2.28}$$

⁵See section 2.2.6 for details on the hierarchy problem and the unification of forces.

and will be described in more detail in section 2.2.4. Gauge mediated supersymmetry breaking happens at lower scales at the order of several TeV; the symmetry breaking is mediated by electroweak and QCD gauge interactions.

2.2.4 mSUGRA

Minimal supergravity grand unification is a proposed model where supersymmetry is a local symmetry. It is called supergravity since in order to achieve local supersymmetry it must include gravity as a fourth interaction in the calculations. In mSUGRA, non-renormalizable interaction terms between the hidden and the visible sector exist, but they are suppressed by $\frac{1}{M_P^x}$, where $x > 1$. mSUGRA assumes that at the GUT scale⁶

$$m_0^2 \mathbf{1} := \mathbf{m}_Q^2 = \mathbf{m}_u^2 = \mathbf{m}_d^2 = \mathbf{m}_L^2 = \mathbf{m}_e^2 \quad (2.29)$$

$$m_0^2 = m_{H_u}^2 = m_{H_d}^2, \quad (2.30)$$

$$m_{1/2} := M_1 = M_2 = M_3 \quad (2.31)$$

$$\mathbf{a}_i = A_0 \mathbf{y}_i, \quad i = u, d, e \quad (2.32)$$

$$b = B_0 \mu. \quad (2.33)$$

A realization of mSUGRA is fully defined by the parameters

$$m_0, m_{1/2}, A_0, b, \mu. \quad (2.34)$$

The masses and parameters at the weak scale can be obtained by using the renormalization group equation (RGE)[12]. Following [9] two relations for b and μ can be derived by minimizing the Higgs potential and by using Eqn. 2.10

$$b = \frac{\left(m_{H_d}^2 - m_{H_u}^2\right) \tan 2\beta + m_Z^2 \sin 2\beta}{2} \quad (2.35)$$

$$\mu^2 = \frac{m_{H_u}^2 \sin^2 \beta - m_{H_d}^2 \cos^2 \beta}{\cos 2\beta} - \frac{m_Z^2}{2}. \quad (2.36)$$

It is possible to determine μ and b from $\tan \beta$ and the sign of μ as the mass of the Z boson m_Z is well measured and the masses m_{H_u} and m_{H_d} are determined by m_0 and the

⁶The GUT scale is defined as the energy scale, where the couplings for the electromagnetic, weak and strong force unite. It is $m_{GUT} \approx 2 \cdot 10^{16}$ GeV[12].

Figure 2.1: Evolution of different supersymmetric particle masses as a function of the renormalization scale Q according to the renormalization group equation[7]. The gaugino and scalar masses are assumed to unite at the GUT scale in mSUGRA-like conditions; the negative mass of H_u leads to a natural breaking of the electroweak symmetry.

renormalization group equation. The set of parameters given in Eqn. 2.34 is thus equivalent to the canonical set of parameters

$$m_0, m_{1/2}, \tan \beta, A_0, \text{sgn} \mu, \quad (2.37)$$

where

- m_0 is the common scalar mass at the GUT scale,
- $m_{1/2}$ is the common gaugino mass at the GUT scale,
- $\tan \beta = v_u/v_d$ is the ratio of the vacuum expectation values of the two Higgs doublets,
- A_0 is the common trilinear coupling at the GUT scale and
- $\text{sgn} \mu$ is the sign of the Higgs mixing parameter.

In this thesis a benchmark point, henceforth called benchmark point BP1, with $m_0 = 60 \text{ GeV}/c^2$, $m_{1/2} = 190 \text{ GeV}/c^2$, $\tan \beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$ is defined to evaluate the sensitivity of the analysis. The benchmark point was chosen to maximize the sensitivity for a trilepton signature at reasonable chargino and neutralino masses.

2.2.5 Neutralinos and Charginos

It was already noted in section 2.2.1 that the supersymmetric partners of the Higgs and gauge bosons, the Higgsinos \tilde{H}_u^+ , \tilde{H}_d^- , \tilde{H}_u^0 , \tilde{H}_d^0 , the Bino \tilde{B}^0 and the Winos \tilde{W}^0 , \tilde{W}^\pm are gauge eigenstates, but not mass eigenstates. The charged particles mix to form the charginos $\tilde{\chi}_i^\pm$, $i = 1, 2$, while the neutral particles mix to form the neutralinos $\tilde{\chi}_i^0$, $i = 1, 2, 3, 4$.

In the basis $(\tilde{B}^0, \tilde{W}^0, \tilde{H}_d^0, \tilde{H}_u^0)$ the neutralino mass matrix is [7]

$$\begin{pmatrix} M_1 & 0 & -g_Y v_d/\sqrt{2} & g_Y v_u/\sqrt{2} \\ 0 & M_2 & g_2 v_d/\sqrt{2} & -g_2 v_u/\sqrt{2} \\ -g_Y v_d/\sqrt{2} & g_2 v_d/\sqrt{2} & 0 & -\mu \\ g_Y v_u/\sqrt{2} & -g_2 v_u/\sqrt{2} & -\mu & 0 \end{pmatrix}, \quad (2.38)$$

where M_1 and M_2 are the MSSM parameters for the Bino and Wino mass and μ is the Higgs mixing parameter from the term $\propto \mu H_u H_d$. The terms in the off-diagonal 2×2 submatrices are the trilinear couplings between gaugino, Higgs and Higgsino. Using Eqn. 2.10, $v_d = v \cos \beta$, $v_u = v \sin \beta$ and the definition of the weak mixing angle $\cos \theta_W = m_W/m_Z$ this can be recast into

$$\begin{pmatrix} M_1 & 0 & -\cos \beta \sin \theta_W m_Z & \sin \beta \sin \theta_W m_Z \\ 0 & M_2 & \cos \beta \sin \theta_W m_Z & -\sin \beta \sin \theta_W m_Z \\ -\cos \beta \sin \theta_W m_Z & \cos \beta \cos \theta_W m_Z & 0 & -\mu \\ \sin \beta \sin \theta_W m_Z & -\sin \beta \cos \theta_W m_Z & -\mu & 0 \end{pmatrix}. \quad (2.39)$$

In the case of the charged Higgsinos and Winos and a gauge eigenstate basis of the form $(\tilde{W}^+, \tilde{H}_u^+, \tilde{W}^-, \tilde{H}_d^-)$ [1] the mass matrix for the charginos can be written as

$$M_{\tilde{\chi}^\pm} = \begin{pmatrix} 0 & X^T \\ X & 0 \end{pmatrix}, \quad \text{where} \quad X = \begin{pmatrix} M_2 & g_2 v_u \\ g_2 v_d & \mu \end{pmatrix} = \begin{pmatrix} M_2 & \sqrt{2} \sin \beta m_W \\ \sqrt{2} \cos \beta m_W & \mu \end{pmatrix}, \quad (2.40)$$

so that the mass term in the Lagrangian can be written as

$$\mathcal{L}_{\text{chargino mass}} = -\frac{1}{2} (\psi^\pm)^T M_{\tilde{\chi}^\pm} \Psi^\pm + \text{c.c.} \quad (2.41)$$

If the relation between the mass and the gauge eigenstates is written as

$$\begin{pmatrix} \tilde{\chi}_1^+ \\ \tilde{\chi}_2^+ \end{pmatrix} = V \begin{pmatrix} \tilde{W}^+ \\ \tilde{H}_u^+ \end{pmatrix} \quad ; \quad \begin{pmatrix} \tilde{\chi}_1^- \\ \tilde{\chi}_2^- \end{pmatrix} = U \begin{pmatrix} \tilde{W}^- \\ \tilde{H}_d^- \end{pmatrix}, \quad (2.42)$$

where U and V are unitary matrices, the mass matrix can be diagonalized by

$$U^* X V^{-1} = \begin{pmatrix} \tilde{\chi}_1^\pm & 0 \\ 0 & \tilde{\chi}_2^\pm \end{pmatrix} \quad (2.43)$$

and the masses at tree-level are

$$m_{\tilde{\chi}_1^\pm}^2, m_{\tilde{\chi}_2^\pm}^2 = \frac{1}{2} \left[|M_2|^2 + |\mu|^2 + 2m_W^2 \mp \sqrt{\left(|M_2|^2 + |\mu|^2 + 2m_W^2\right)^2 - 4|\mu M_2 - m_W^2 \sin 2\beta|^2} \right]. \quad (2.44)$$

If the gaugino masses and the gauge couplings are assumed to unify at the GUT scale, it is^[12]

$$\frac{M_3}{g_s^2} = \frac{M_2}{g_2^2} = \frac{M_1}{5/3 g_Y^2} = \frac{m_{1/2}}{g^2(M_{GUT})} \quad (2.45)$$

invariant under application of the renormalization group equation⁷. Using Eqn. 2.10 this implies that

$$\frac{M_1(m_Z)}{M_2(m_Z)} = \frac{5}{3} \tan^2 \theta_W \approx \frac{1}{2}. \quad (2.46)$$

In the limit of $|\mu| \gg |M_i| \gg m_Z$, $i = 1, 2$ the lightest neutralino $\tilde{\chi}_1^0$ is mostly the Bino; the next to lightest neutralino $\tilde{\chi}_2^0$ is mostly the neutral Wino and the neutralinos $\tilde{\chi}_i^0$, $i = 3, 4$, are mostly neutral Higgsinos. The lighter chargino $\tilde{\chi}_1^\pm$ is mostly the charged Wino, whereas the heavier chargino is mostly the charged Higgsino. Furthermore

$$m_{\tilde{\chi}_1^\pm} \approx m_{\tilde{\chi}_2^0} \approx 2 \cdot m_{\tilde{\chi}_1^0}, \quad |\mu| \approx m_{\tilde{\chi}_3^0} \approx m_{\tilde{\chi}_4^0} \approx m_{\tilde{\chi}_2^\pm} \gg m_{\tilde{\chi}_1^\pm} \quad (2.47)$$

following Eqn. 2.46.

In the limit of $|\mu| \ll |M_i|$, $i = 1, 2$, the neutralinos $\tilde{\chi}_i^0$, $i = 1, 2$, are mostly the neutral Higgsinos; the neutralinos $\tilde{\chi}_i^0$, $i = 3, 4$, are the Bino and neutral Wino whereas the lighter

⁷The factor 5/3 comes from the difference between the GUT normalization and the usual SM normalization of the hypercharge generator^[12].

chargino $\tilde{\chi}_1^\pm$ is mostly the charged Higgsino and the heavier chargino $\tilde{\chi}_2^\pm$ mostly the charged Wino. Following Eqn. 2.46

$$m_{\tilde{\chi}_1^\pm} \approx m_{\tilde{\chi}_1^0} \approx m_{\tilde{\chi}_2^0} \approx |\mu|, \quad 2 \cdot m_{\tilde{\chi}_3^0} \approx m_{\tilde{\chi}_4^0} \approx m_{\tilde{\chi}_2^\pm}. \quad (2.48)$$

The relevant couplings of the chargino and neutralino components are listed in Fig. 2.2. It has to be noted that the charged Wino \tilde{W}^\pm couples only to left-handed sleptons and that the Higgsino \tilde{H} has a Yukawa coupling to third generation particles. The actual decays of the neutralinos and charginos depend strongly on the mass spectrum and the kinematically allowed decay channels. The relevant possible two-body decay channels of the neutralino are

$$\tilde{\chi}_i^0 \rightarrow \tilde{\chi}_j^0 Z^0, \quad (2.49)$$

$$\tilde{\chi}_i^0 \rightarrow \tilde{\chi}_j^\pm W^\pm, \quad (2.50)$$

$$\tilde{\chi}_i^0 \rightarrow \tilde{l}^\pm l^\mp, \quad (2.51)$$

$$\tilde{\chi}_i^0 \rightarrow \tilde{\nu}_l \nu_l, \quad (2.52)$$

$$\tilde{\chi}_i^0 \rightarrow \tilde{\chi}_j^0 h^0, \quad (2.53)$$

where $l = e, \mu, \tau$. Sleptons and sneutrinos subsequently mostly decay according to

$$\tilde{\nu}_l \rightarrow \tilde{\chi}_i^0 \nu_l, \quad (2.54)$$

$$\tilde{l}^\pm \rightarrow \tilde{\chi}_i^0 l^\pm. \quad (2.55)$$

Decays of the neutralinos into $\tilde{\chi}_j^0 A^0$, $\tilde{\chi}_j^0 H^0$, $\tilde{\chi}_j^\mp H^\pm$ and $\tilde{q}q$ are possible for the right choice of the supersymmetric parameters, but not dominant for the parameter space considered in this thesis. If neither of the two-body decay channels is kinematically allowed, usually a three-body decay via off-shell Z^{0*} boson happens according to

$$\tilde{\chi}_i^0 \rightarrow \tilde{\chi}_j^0 Z^{0*} \rightarrow \tilde{\chi}_j^0 \begin{cases} l^+ l^- \\ q \bar{q} \\ \nu_l \bar{\nu}_l \end{cases}. \quad (2.56)$$

Figure 2.2: Relevant allowed vertices for the decay of chargino and neutralino into leptons

The decays of the charginos are similar with the decay channels

$$\tilde{\chi}_i^\pm \rightarrow \tilde{\chi}_j^0 W^\pm, \quad (2.57)$$

$$\tilde{\chi}_i^\pm \rightarrow \tilde{\chi}_j^\pm Z^0, \quad (2.58)$$

$$\tilde{\chi}_i^\pm \rightarrow \tilde{l}^\pm \nu_l, \quad (2.59)$$

$$\tilde{\chi}_i^\pm \rightarrow \tilde{\nu}_l l^\pm, \quad (2.60)$$

where the slepton and sneutrino subsequently decay according to Eqns. 2.54 and 2.55. Decays into $\tilde{\chi}_j^\pm h^0$, $\tilde{\chi}_j^\pm A^0$, $\tilde{\chi}_j^\pm H^0$, $\tilde{\chi}_j^0 H^\pm$ and $\tilde{q}_1 \bar{q}_2$ are possible, but not dominant for the parameter space considered in this thesis. If none of the two-body decay channels is kinematically allowed usually a three-body decay via off-shell $W^{\pm*}$ boson happens according to

$$\tilde{\chi}_i^\pm \rightarrow \tilde{\chi}_j^0 W^{\pm*} \rightarrow \tilde{\chi}_j^0 \begin{cases} l^\pm \nu_l \\ q_1 \bar{q}_2 \end{cases}. \quad (2.61)$$

2.2.6 Supersymmetry and the Limitations of the Standard Model

High energy physics experiments have tested the Standard Model of Particle Physics in collisions up to a center-of-mass energy of 1.96 TeV, which can currently be reached at the Tevatron accelerator at Fermilab. The predictions of the Standard Model agree very well with the experimental results and additional structure has not yet been seen. However, the Standard Model of Particle Physics has at least 18 free parameters⁸ and an underlying, more fundamental theory is expected. Furthermore there are several open questions that are not addressed by the Standard Model.

⁸It should be noted that general MSSM has 110 free parameters and thus might not be considered a fundamental theory.

The Hierarchy Problem

Figure 2.3: Fermionic and sfermionic loop contributions to the scalar Higgs mass

In Eqn. 2.4 a term proportional to $(\phi^\dagger \phi)^2$ was introduced into the Lagrangian to ensure electroweak symmetry breaking. If the mass of the Higgs boson is calculated, 1-loop level contributions from fermionic and scalar loops have to be considered. An example of a fermionic loop can be found in Fig. 2.3. For an interaction term of the form $-\lambda_f H \bar{f} f$ the contribution of the fermionic loop to the Higgs mass in Landau notation is

$$\Delta m_H^2 = -\frac{|\lambda_f|^2}{8\pi^2} \Lambda^2 + \mathcal{O}\left(\ln\left(\frac{\Lambda}{m_f}\right)\right) [7], \quad (2.62)$$

where Λ is a cutoff parameter for the applicability of the Standard Model and m_f is the mass of the fermion in the loop. The bare mass of the Higgs boson can be obtained from Eqn. 2.4 as

$$m_0^2 = 2\mu^2 = -2\lambda v^2, \quad (2.63)$$

so that the Higgs mass is $m_H^2 = m_0^2 + \sum_{\text{all loops}} \Delta m_H^2$. Based on data collected at the LEP experiment the Higgs mass was constrained at 95% confidence level to

$$114.4 \text{ GeV}/c^2 < m_H < 193 \text{ GeV}/c^2 \quad (2.64)$$

in [13, 14]. As the cutoff for new physics Λ is very large in order to get a Higgs mass in this allowed interval, a cancellation of the mass corrections and the bare Higgs mass is needed. In supersymmetric models a cancellation happens naturally as the contributions by Standard Model particles are canceled by the contributions of supersymmetric particles. Without supersymmetric particles the cancellation of the bare mass and the corrections is regarded unnatural. This is known as the hierarchy or the fine-tuning problem.

Unification of Forces

In quantum field theory coupling constants are defined by

$$\alpha = \frac{g_x^2}{2\pi}, \quad (2.65)$$

where g_x is an energy dependent coupling parameter. As the values of the coupling parameters are known to high precision at the scale $Q = M_Z$ [\[1\]](#) their value at arbitrary scale can be obtained by application of the renormalization group equation. The renormalization group equation at 1-loop order is[\[7\]](#)

$$\frac{d}{dt}g_a = \frac{1}{16\pi^2}b_a g_a^3, \quad \text{where } b_{1,2,3} = \begin{cases} (41/10, /19/6, -7) & \text{Standard Model} \\ (33/5, 1, -3) & \text{MSSM} \end{cases}, \quad (2.66)$$

$t = \ln(Q/Q_0)$ and Q_0 is a high energy scale, where different contributions to the Lagrangian are assumed. The evolution of the gauge couplings as a function of the scale Q is shown in [Fig. 2.4](#). It can be seen, that the couplings do not fully unite in the SM evolution, whereas in the MSSM evolution supersymmetric loop contributions have to be considered and the couplings unite at the precision of the figure.

Figure 2.4: Inverse gauge coupling evolution as a function of the renormalization scale Q according to the renormalization group equation for the Standard Model (dashed lines) and the MSSM (solid lines). In the MSSM case, the sparticle mass thresholds are varied between 250 GeV and 1 TeV, and $\alpha_3(m_Z)$ between 0.113 and 0.123. Two-loop effects are included[\[7\]](#).

Dark Matter and Dark Energy

The Friedmann equation is[15]

$$H^2 = \frac{\dot{R}^2}{R^2} = \frac{8\pi G_N}{3}\rho - \frac{kc^2}{R^2}, \quad (2.67)$$

where H is the Hubble constant, R an arbitrary length, which is used as a measure for the metric of the universe, G_N Newton's gravitational constant and k a constant that is -1 for an open, 0 for a flat and 1 for a geometrically closed universe. The Friedmann equation describes the time evolution and the geometry of the universe and is strongly dependent on the density of the universe ρ . For the critical density

$$\rho_c = \frac{3H^2}{8\pi G_N} \quad (2.68)$$

the universe is flat. The density parameter of the universe is defined by

$$\Omega_m = \frac{\rho}{\rho_c}. \quad (2.69)$$

Ω_b , defined by $\Omega_b = \rho_b/\rho_c$, where ρ_b is the baryonic density, is called the baryonic density parameter; Ω_c is the cold dark matter density parameter, so that $\Omega_m = \Omega_b + \Omega_c$, where Ω_m is the density parameter for all matter. Dark matter is matter that does not take part in the electromagnetic and strong interactions, but can be observed by its gravitational interaction. The Friedmann equation in the form of Eqn. 2.67 describes a decelerating universe; Einstein introduced the term $-\frac{1}{3}\Lambda c^2$ where Λ is the cosmological constant. The cosmological constant can be interpreted as acceleration due to dark energy. The density parameter is given by $\Omega_\Lambda = \frac{\Lambda}{3H_0^2}$.

The Wilkinson Microwave Anisotropy Probe (WMAP) is a satellite which recorded the cosmic microwave background. A six parameter cosmological model is fit to the data and together with measurements from Type Ia supernovae the following results can be obtained[16]:

$$\Omega_b = 0.0462 \pm 0.0015 \quad (2.70)$$

$$\Omega_c = 0.233 \pm 0.013 \quad (2.71)$$

$$\Omega_\Lambda = 0.721 \pm 0.015 \quad (2.72)$$

From Eqns. 2.70 to 2.72 it can be derived that baryonic matter makes up less than 5% of the energy and less than 20% of the matter in the universe.

It is still unknown what dark matter is made of. The Standard Model does not offer particles that might make up dark matter. In the case of conserved R-parity the lightest supersymmetric particle is stable and in the case of a neutral LSP it can serve as a dark matter candidate. In big regions of the MSSM parameter space the lightest neutralino is an uncharged and color neutral LSP and is thus able to make up dark matter.

A review on reasons to judge if supersymmetry might be the answer to outstanding problems of the Standard Model can be found in [17].

Chapter 3

The Experimental Apparatus

This analysis is using data collected by the Collider Detector at Fermilab in the configuration of Run II (CDF II) detector. The CDF detector is one of two multipurpose detectors that use 1.96 TeV proton-antiproton collisions taking place in the Tevatron accelerator at the Fermi National Accelerator Laboratory (FNAL, Fermilab). Until the Large Hadron Collider is in operation Fermilab houses the world's most energetic operating particle accelerator.

Figure 3.1: Aerial view of the Tevatron (top) and the Main Injector (bottom). Robert Rathbun Wilson Hall (“The High Rise”), the main office and laboratory building, is in the top left. The CDF Detector Hall is the red building next to the Tevatron ring.

Figure 3.2: Artistic illustration of the accelerator chain at Fermilab.

Figure 3.3: Integrated luminosity delivered by the Tevatron accelerator as of August 20, 2008^[18].

3.1 The Tevatron and its Preaccelerators

At Fermilab hydrogen is ionized and accelerated in a magnetron to 25 keV. The resulting H^- ions are passed to a Cockcroft-Walton preaccelerator, a voltage multiplier, which by using a constant voltage accelerates the H^- ions to 750 keV and inserts them into the Linac, an approximately 150 m long linear accelerator. The Linac uses oscillating electric fields to reach an energy of 400 MeV. At the end of the Linac the H^- ions beam crosses a carbon foil and electrons are stripped off, so that a proton beam can be separated. The proton beam is passed into the Booster, the first circular accelerator. Having a circumference of 475 m it accelerates the protons to an energy of 8 GeV. From the Booster the proton beam is inserted into the Main Injector, which fulfills three functions: It can accelerate protons to an energy of 150 GeV and insert them into the Tevatron; it can accelerate protons to an energy of 120 GeV and shoot them into a nickel target to produce antiprotons and it can accelerate previously produced antiprotons to 150 GeV and insert them into the Tevatron. When shot into a nickel target a 120 GeV proton beam produces antiprotons with different energies and angles among a lot of other secondary particles. Antiprotons with an energy of approximately 8 GeV are focused by a lithium lense and cooled and stacked in the Debuncher and the Accumulator. The production of antiprotons has always been one of the main limiting factors for the Tevatron operation. For this reason the Recycler ring was built in the tunnel of the Main Injector. The Recycler's role is to store antiprotons from the Accumulator and cool them further down to increase the antiproton stacking rate. Unlike the Accumulator the Recycler's magnet system can store antiprotons efficiently for a longer time. Additionally the Recycler was designed to store antiprotons that are left over from previous Tevatron runs, however, this operation mode is currently not used.

The Tevatron finally accelerates protons and antiprotons to an energy of approximately 1 TeV, so that a center-of-mass energy of $\sqrt{s} = 1.96 \text{ TeV}$ can be reached in a proton-antiproton collision. In the Tevatron protons and antiprotons are ordered in 140 and 103 bunches respectively[19] and are accelerated separately, so that they collide in the two multi-purpose detectors CDF and DØ at the sector points B0 and D0. Every proton bunch consists of approximately 2.7×10^{11} protons and every antiproton bunch of approximately

1.0×10^{11} antiprotons at a length of 37 cm. The bunches have a separation of 132 nsec. Integrated Luminosity is a measure for the number of collisions that have been delivered. The Tevatron currently delivers a peak luminosity of[18]

$$\mathcal{L} \approx 3.2 \times 10^{32} \frac{1}{\text{cm}^2 \text{s}} = 3.2 (\mu\text{b})^{-1}, \quad (3.1)$$

which currently leads to a weekly integrated luminosity of

$$\int_{1 \text{ week}} \mathcal{L}(t) dt \approx 5.5 \times 10^{37} \frac{1}{\text{cm}^2 \text{s}} = 55 (\text{pb})^{-1}. \quad (3.2)$$

3.2 The Collider Detector at Fermilab

Figure 3.4: Photo of the Collider Detector at Fermilab with opened plug

The Collider Detector at Fermilab (CDF II¹)[20, 21] is one of two multipurpose detectors at the Tevatron. It is built symmetrically in azimuthal direction around the Tevatron beamline, is measuring approximately $12 \text{ m} \times 12 \text{ m} \times 12 \text{ m}$ and weighing approximately 1000 metric tons. Figure 3.5 shows a schematic drawing of the CDF II detector. Starting at the Tevatron beamline the CDF II detector's main components are the tracking system, the solenoid, the electromagnetic and the hadronic calorimeters and the muon detector system.

¹The Collider Detector at Fermilab was updated after the end of Run I. The name CDF II refers to the configuration of the detector in Run II.

The solenoid generates a 1.4 T magnetic field, which bends the tracks of charged particles, so that their momentum can be determined in the tracker.

The CDF coordinate system is uniquely defined by the coordinates (r, θ, ϕ) which is equivalent to (r, η, ϕ) , where

the **radius** r is measured from the center of the detector,

the **polar angle** θ is measured from the beamline direction,

the **azimuthal angle** ϕ is measured from the plane defined by the Tevatron ring and

the **pseudorapidity** η is defined by $\eta = -\ln \tan \frac{\theta}{2}$.

Figure 3.5: Parts of the Collider Detector at Fermilab (CDF). L00: Layer 00 silicon tracker, SVX: Silicon Vertex detector, ISL: Intermediate Silicon Layers, COT: Central Outer Tracker, CEM: Central ElectroMagnetic calorimeter, CES: Central Electromagnetic Strip chamber, CHA: Central HAdronic calorimeter, CMU: Central MUon detector, CMP: Central Muon uPgrade detector, CSP: Central muon Scintillator uPgrade, CMX: Central Muon eXtension detector, CSX: Central muon eXtension Scintillators

3.2.1 The Tracking System

Figure 3.6: Longitudinal view of the CDF II tracking system[20] and parts of the calorimeter. The Layer 00 tracking system is the grey line below the SVX.

The CDF Tracking system is shown in Fig. 3.6 and consists of the silicon detectors Layer 00, the Silicon Vertex Detector, the Intermediate Silicon Layers and a proportional wire chamber, the Central Outer Tracker.

The Silicon Tracker

In silicon detectors charged particles produce electron-hole pairs. If a voltage is applied, a current can be measured and, for several read-out channels, a particle track can be reconstructed. The Layer 00 tracking system is a single-sided silicon layer starting at 1.35 cm around the center of the beam pipe. Around the Layer 00 tracker the Silicon Vertex Detector (SVX) was built. It consists of 5 double-sided silicon layers placed from 2.44 cm to 10.6 cm. Whereas single-sided silicon layers only have a one-dimensional resolution, double-sided silicon layers have two layers rotated by 90° (for three of five layers) or 1.2° (small angle stereo for two layers) towards each other to provide a two-dimensional resolution. In the region $|\eta| < 1$ full 3D track reconstruction is possible, if tracks in the Silicon Vertex Detector and the Central Outer Tracker are matched. For $\eta > 1$ the SVX can provide only

2D vertex reconstruction. The Intermediate Silicon Layers (ISL) are additional single silicon layers, which are placed at 22 cm for $|\eta| < 1$ and at 20 cm and 28 cm around the beamline for $1 < |\eta| < 2$. The main design goals of the L00, the SVX and the ISL layers were to reach a precise impact parameter, secondary vertex and z_0 measurement. The impact parameter d_0 is the distance of the particle's track to the beamline in the (r, ϕ) -plane; secondary vertex measurement is needed for B-tagging ability and z_0 is the distance from the intersection of the interpolation of the track and the beamline to the center of the detector. The silicon tracking system can provide a hit resolution of $11 \mu\text{m}$ (L00) and $9 \mu\text{m}$ (SVX) which results in an impact parameter resolution of $40 \mu\text{m}$, where $30 \mu\text{m}$ contribution from the beamline is included. The z_0 resolution is $70 \mu\text{m}$ [22].

The Central Outer Tracker

The Central Outer Tracker is an open cell drift chamber located from 40 cm to 138 cm around the beampipe. Charged particles can ionize gas atoms and in an electric field, the produced particles can drift to the anode or cathode respectively and induce a current. The Central Outer Tracker is built of a gold covered polyester cathode plate and gold covered tungsten wires as anode in several cells. These are filled with Argon : Ethane gas in a 50 : 50 mixture with small amounts of isopropyl alcohol to obtain a good drift time. To obtain a better spatial resolution than the COT cell size the drift time, which is proportional to the distance to the hit, is measured. However, only based on drift time there is no information on which side the track has passed the sense wire. Together with the information of other cells the full track can nevertheless be reconstructed. The position resolution for a hit in the COT is $140 \mu\text{m}$. The momentum resolution is

$$\sigma_{p_T}/p_T = \begin{cases} 0.15\% \times p_T/\text{GeV} & \text{COT only} \\ 0.07\% \times p_T/\text{GeV} & \text{COT + SVX + ISL} \\ 0.05\% \times p_T/\text{GeV} & \text{COT beam-constrained} \end{cases}, \quad (3.3)$$

where beam-constrained assumes that the track originates in the beamline.

3.2.2 The Calorimeter

The calorimeter of the CDF detector can be divided into central ($|\eta| < 1.1$), end wall and end plug calorimeter ($1.1 < |\eta| < 3.6$). The naming scheme of the reconstructed objects, e.g. central or plug electrons reflects these calorimeter parts. A schematic drawing of the calorimeter can be found in Fig. 3.7. If particles travel through calorimeter material, they interact with its atoms by several processes such as ionization, bremsstrahlung, the photoelectric effect, Compton scattering, pair production and nuclear processes. Finally electrons, photons and hadrons can lose all their energy into heat and light; muons are minimum ionizing particles and do not lose their full energy in the limited space that a calorimeter can take. A calorimeter mostly consists of several layers of absorber material, where interaction and scintillation layers alternate². The light released by processes in the scintillation layers is collected and can be related to the energy of the incident particle. The interaction of electrons or photons and hadrons with matter is different; materials with high proton number Z and low mass number A are used to measure electromagnetic energy³, whereas materials with high mass number A are used to measure hadronic energy.

The Electromagnetic Calorimeter

The central electromagnetic calorimeter is located inside the hadronic calorimeter and consists of towers and wedges with a size of 15° in azimuthal direction and 0.11 in pseudorapidity. Each wedge is built as a sampling calorimeter and made of lead absorbing and polystyrene scintillator material. The Central PreRadiator (CPR), a wire chamber located between the solenoid and the CEM, and the Central Electromagnetic Strip chamber (CES), a shower maximum detector based on a multiwire proportional counter in the middle of the CEM, help to differentiate electrons and photons using the position measurement to

²Interaction layers are present for sampling calorimeters, but not for homogeneous calorimeters.

³Electrons and photons deposit most of their energy in the electromagnetic calorimeter; hadrons deposit most of their energy in the hadronic calorimeter

Figure 3.7: The CDF calorimeter system is consisting of the Central ElectroMagnetic calorimeter (CEM), the Central HAdronic calorimeter (CHA), the endWall HAdronic calorimeter (WHA), the endPlug ElectroMagnetic calorimeter (PEM) and the endPlug HAdronic calorimeter (PHA).

match calorimeter deposits with tracks and to differentiate photons from π^0 's based on the transverse shower profile. The energy resolution of the CEM is

$$\sigma_E/E = 13.5\% \frac{1}{\sqrt{E_T/\text{GeV}}} + 2\%. \quad (3.4)$$

The Hadronic Calorimeter

The Central HAdronic calorimeter (CHA) is a sampling calorimeter based on absorbing iron and scintillating acrylic glass material and is located outside of the CEM. The energy resolution of the CHA is

$$\sigma_E/E = 50\% \frac{1}{\sqrt{E_T/\text{GeV}}} + 3\%. \quad (3.5)$$

3.2.3 The Muon Chambers

The muon chambers are single wire tracking chambers located behind the calorimeters. Muons are minimum ionizing particles that hardly interact with the calorimeter and pass through the calorimeter material; all other particles are usually stopped in the calorimeter material. It can be assumed that every measured track outside of the calorimeter comes from a muon, however, there is background from so-called non-interacting punch through, other particles, mostly pions, that have been able to pass the calorimeter. The muon system consists of four parts: the Central MUon detector (CMU), the Central Muon uPgrade detector (CMP), the Central Muon eXtension detector (CMX) and the Intermediate MUon chambers (IMU), which are made of the Toroid Scintillator Upgrade (TSU), the Barrel MUon detector (BMU) and the Barrel Scintillator Upgrade (BSU). The (η, ϕ) coverage of these detector systems can be seen in Fig. 3.8.

The Central Muon Detector

The Central MUon detector (CMU) covers the region where $|\eta| < 0.6$ and is built from $6.35 \text{ cm} \times 2.68 \text{ cm} \times 226 \text{ cm}$ cells with a $50 \mu\text{m}$ stainless steel wire in the middle. If charged particles pass through the cell, they produce ions and a current pulse can be measured in the sense wire. The CMU consists of four radial cell layers, where the first and third,

Figure 3.8: Coverage of the CDF muon detectors in the (η, ϕ) -plane. CMU: Central MUon detector, CMP: Central Muon uPgrade detector, CMX: Central Muon eXtension detector, IMU: Intermediate MUon chambers consisting of the Toroid Scintillator Upgrade (TSU), the Barrel MUon detector (BMU) and the Barrel Scintillator Upgrade (BSU)

second and fourth layers have a slight offset in ϕ to get a multidimensional resolution. The minimum detectable muon p_T is 1.4 GeV.

The Central Muon uPgrade Detector

The Central Muon uPgrade detector (CMP) is located behind an extra layer of 60 cm steel and, similar to the CMU, consists of a single wire drift chamber, which is operated in proportional mode and covers most of the region where $|\eta| < 0.6$. Unlike the CMU, the CMP detector also includes a layer of scintillation counters with connected photomultiplier tubes, which are located on the outer side of the CMP and provide timing information for the CMP hits.

The Central Muon Extension Detector

The CMX is the outer-most muon system. It is built in a similar design to the CMP, consists of drift tubes and scintillation counter and covers the region where $0.6 < |\eta| < 1.0$. It can be seen in Fig. 3.8 that the CMX detector has a 30° gap in the ϕ coverage to provide space for the Tevatron main ring and the solenoid refrigerator.

3.2.4 The Trigger System

At CDF events happen at a rate of several million per second even though the number of stored events has to be less 100 per second. Triggers are hardware and software components that decide which events may provide interesting physics information and are thus stored. CDF has implemented a three stage trigger system:

- Level 1 is a synchronous hardware trigger, which reduces the event input rate from 1.7 MHz to 25 kHz. It makes decisions based on fast inputs.
- Level 2 is an asynchronous mixed hard- and software trigger even though the software components are dominant. It reduces the event input rate from 25 kHz to 550 Hz. The level 2 trigger performs a limited event reconstruction.
- Level 3 is a software farm which reduces the event input rate from 550 Hz to 120 Hz. At the stage of the level 3 trigger a full event reconstruction is done.

3.3 Datasets used in this Analysis

For this analysis we use the following trigger datasets:

- high p_T central electron (bhel*), where one central electron with $p_T > 18 \text{ GeV}$ is required,
- high p_T muon (bhmu*), where one CMUP or one CMX muon with $p_T > 18 \text{ GeV}$ is required,
- SUSY dilepton (edil*), where two electrons or two muons with $p_T > 4 \text{ GeV}$ for each lepton ($p_T > 8, 4 \text{ GeV}$ for the last 191 pb^{-1} of data) is required.

The changed requirements for the SUSY dilepton dataset have no influence on our lepton selection due to higher thresholds in the definition of the analysis channels⁴. Runlist version 18 with option (1, 0, 4, 1) is used to determine good runs as we require the electromagnetic calorimeter and the muon system to be operating normally. After using the runlist there are 3636 good runs remaining, which correspond to a luminosity of 2008 pb^{-1} for the high p_T electron triggers. We apply correction factors

1. of 1.019 for the historical interpolation of the inelastic cross section between Run I ($\sqrt{s} = 1.8 \text{ TeV}$) and Run II ($\sqrt{s} = 1.96 \text{ TeV}$)[23] and
2. for a cut of $|z_0| < 60 \text{ cm}$ [24]⁵. The correction factor is 0.958 for data taking periods 0 to 7, 0.968 for periods 8 to 11 and 0.972 for periods 12 and 13.

It is conventional to quote the integrated luminosity after the correction for the interpolation of the inelastic cross section. The integrated luminosity used by this analysis is

$$\int \mathcal{L} dt = 2046 \text{ pb}^{-1} \quad (3.6)$$

for the high p_T electron trigger. Different luminosities of the other triggers are absorbed into the trigger efficiencies. For example, if a trigger was present for only corrected 500 pb^{-1}

⁴See Table 4.6 for details

⁵For details see section 4.2.2.

of 2046 pb^{-1} and the efficiency of its path A taken by lepton i is ϵ , we take its efficiency to be

$$\epsilon_{i,A}^{\text{corr}} = \epsilon \times \frac{500}{2046}. \quad (3.7)$$

The uncorrected trigger efficiencies for the high p_T electron and muon dataset and the SUSY dilepton dataset have been measured in [25, 26, 27, 28, 29, 30] as a function of lepton E_T . The trigger efficiency for an event is

$$\epsilon_A^{\text{event}} = 1 - \sum_{i=1}^n \prod_{j \neq i} (1 - \epsilon_{j,A}) + (n-1) \prod_{i=1}^n (1 - \epsilon_{i,A}), \quad (3.8)$$

where n is the number of identified leptons, the second term is the efficiency for one lepton to fire the trigger and the third term compensates double-counting.

3.4 Monte Carlo Samples used in this Analysis

Sample	Generator	$\sigma \times \text{BR} / \text{pb}$	$\mathcal{L} / \text{fb}^{-1}$
DY, $Z/\gamma^* \rightarrow ee$	Pythia	355×1.4	19.8
DY, $Z/\gamma^* \rightarrow \mu\mu$	Pythia	355×1.4	20.3
DY, $Z/\gamma^* \rightarrow \tau\tau$	Pythia	355×1.4	18.7
$Z\gamma \rightarrow ee\gamma$	Baur	10.33×1.36	409
$Z\gamma \rightarrow \mu\mu\gamma$	Baur	10.33×1.36	405
$Z\gamma \rightarrow \tau\tau\gamma$	Baur	10.33×1.36	408
WW	Pythia	1.27	404
WZ	Pythia	0.208	559.6
ZZ	Pythia	2.116	491.8
$t\bar{t}$	Pythia	6.9	593.0

Table 3.1: Monte Carlo background samples. Diboson samples include the decay of off-shell particles.

Monte Carlo samples for the background estimation were produced with the generators in Table 3.1. For signal Monte Carlo we use the CDF MC PRODUCTION 6.1.4mc standard MC tarballs with PYTHIA 6.409[31] (6.216)⁶, parton distribution function CTEQ5L[32], spectrum calculated by ISASUGRA from ISAJET 7.75[33] (7.51)⁶ and τ decays by TAUOLA[34]. Cross

⁶For a detailed discussion of the used versions of ISAJET and PYTHIA see appendix B.

sections for supersymmetric processes are calculated at next to leading order with PROSPINO 2.0[35].

In the analysis section of this thesis the signal predictions are obtained from a Monte Carlo sample produced with mSUGRA parameters as defined as benchmark point BP1 in section 2.2.4 with the parameters

- $m_0 = 60 \text{ GeV}/c^2$
- $m_{1/2} = 190 \text{ GeV}/c^2$
- $\tan \beta = 3$
- $A_0 = 0 \text{ GeV}$
- $\mu > 0$.

Chapter 4

The Trilepton Analysis

The basis of this thesis is a search for supersymmetric chargino-neutralino production in the three leptons and missing transverse energy final state. Setup as an unbiased counting experiment, several channels based on lepton flavor are defined and the number of events observed in data of the CDF II detector is compared with the expectation for the Standard Model background.

4.1 The Trilepton Signature

Figure 4.1: Cross sections at next-to-leading order precision for the production of different chargino-chargino, chargino-neutralino and neutralino-neutralino pairs in $p\bar{p}$ $\sqrt{s} = 1.96$ TeV collisions at the Tevatron. The cross sections for the production of pairs of the form $\tilde{\chi}_i^0 \tilde{\chi}_j^\pm$ are the sum for the cross sections for positively and negatively charged chargino production. The mass spectrum was calculated with ISAJET 7.75 in mSUGRA as a function of $m_{1/2}$ at benchmark point BP1; the cross section was calculated with PROSPINO 2.0.

At the Tevatron associate production of chargino $\tilde{\chi}_1^\pm$ and neutralino $\tilde{\chi}_2^0$ can happen in $p\bar{p}$ collisions. The s-channel production occurs via exchange of an off-shell $W^{\pm*}$ boson; the t-channel production via exchange of an off-shell squark \tilde{q}^* . The s- and t-channel interfere destructively; for high squark masses the t-channel production is suppressed and the cross section increases[36]. Feynman diagrams for the production channels can be found in Fig. 4.2. The production cross section for $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ at benchmark point BP1¹ at the precision of a next to leading order calculation with PROSPINO 2.0[35]² is

$$\sigma = (0.500 \pm 0.050) \text{ pb}, \quad (4.1)$$

so that for an integrated luminosity $\int \mathcal{L} dt = 2.0 \text{ fb}^{-1}$ a total of 1000 $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ events are expected for direct production. This search is focusing on the leptonic decay of chargino

Figure 4.2: Leading order Feynman diagrams for the associated production of chargino and neutralino in $p\bar{p}$ collisions

and neutralino. Figure 4.3 shows the dominant leptonic decays of chargino and neutralino

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (4.2)$$

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\tau}_1^\pm \nu_\tau \rightarrow \tilde{\chi}_1^0 \tau^\pm \nu_\tau \quad (4.3)$$

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\nu}_l l^\pm \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (4.4)$$

$$\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \tilde{\chi}_1^0 l^+ l^- \quad (4.5)$$

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^-, \quad (4.6)$$

where $l = e, \mu, \tau$ and $\tilde{l}_R^\pm = \tilde{e}_R^\pm, \tilde{\mu}_R^\pm, \tilde{\tau}_1^\pm$. The decay of the chargino into right-handed selectrons and smuons is highly suppressed. The chargino is a mixed mass eigenstate with a charged Wino and a Higgsino component; Fig. 2.2 shows the couplings of the Higgsino and charged

¹mSUGRA $m_0 = 60 \text{ GeV}/c^2$, $m_{1/2} = 190 \text{ GeV}/c^2$, $\tan \beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$

²The error calculated by PROSPINO is too low; a 10% error is assumed[37].

Wino component of the chargino. The charged Wino component couples to left-handed sleptons only. As there is very low mixing of the left- and right-handed selectrons and smuons the coupling of the chargino's Wino component to the lighter selectron and smuon is negligible. The lighter stau $\tilde{\tau}_1$ is a mixture of the left- and right-handed stau and the charged Wino can couple to the left-handed component of the $\tilde{\tau}_1$. The Higgsino component of the chargino couples via a Yukawa term to sleptons. In the approximation of Eqn. 2.20 the coupling of the Higgsino to selectron and smuon is negligible, whereas there is a non-negligible coupling to the stau. A more detailed analysis of the chargino and neutralino branching ratios as a function of the mSUGRA parameters can be found in section 5.1.

As the lightest supersymmetric particles $\tilde{\chi}_1^0$ and the neutrino ν_l escape the detector undetected and result in missing transverse energy, the signature for the leptonic decay of chargino and neutralino in Eqns. 4.2 to 4.6 is three leptons and missing transverse energy, the so-called trilepton signature. One lepton comes from the decay of the chargino; two leptons from the decay of the neutralino. The production of chargino and neutralino in the trilepton channel is one of the most promising searches for supersymmetry at the Tevatron and is often referred to as the “golden” channel. [38] is examining several final states of supersymmetric interaction in a constrained MSSM model for their discovery at the Tevatron.

4.2 Event Reconstruction

Electrons and muons can be identified directly based on their signals in the tracker, the calorimeter and the muon system, however τ leptons decay in the detector and can only be identified via their decay products. A list of the decay channels of the τ lepton and their branching ratios can be found in Table 4.1. If the τ lepton decays into an electron or a muon, it is possible to identify them in the respective categories provided that they pass the quality criteria. In approximately 50% of all cases the τ lepton decays into a hadronic one-prong final state. In order to get sensitivity to this hadronic one-prong decay of the τ lepton the analysis is identifying isolated tracks. The isolation criterion is needed to suppress background; three-prong decays usually do not pass the isolation criterion.

Figure 4.3: Dominant decay channels of the neutralino $\tilde{\chi}_2^0$ and the chargino $\tilde{\chi}_1^\pm$ into leptons. It is $l = e, \mu$.

$\tau^- \rightarrow$	BR
one-prong decay	85.4%
$\mu^- \bar{\nu}_\mu \nu_\tau$	17.4%
$e^- \bar{\nu}_e \nu_\tau (+\gamma)$	17.9%
$\pi^- \nu_\tau$	10.9%
$\pi^- \pi^0 \nu_\tau$	25.5%
$\pi^- \pi^0 \pi^0 \nu_\tau$	9.3%
$\pi^- \pi^0 \pi^0 \pi^0 \nu_\tau$	1.0%
$X^- \nu_\tau$	1.2%
$K(892)^- \nu_\tau$	1.2%

$\tau^- \rightarrow$	BR
three-prong decay	14.6%
$\pi^- \pi^+ \pi^- \nu_\tau$	9.3%
$\pi^- \pi^+ \pi^- \pi^0 \nu_\tau$	4.6%
five-prong decay	0.1%

Table 4.1: Branching ratios for the different decay channels of the τ^- lepton according to [1]. Decay channels with branching ratio smaller than 1% are neglected.

4.2.1 Event Vertex

The event or primary vertex is defined as the place where the $p\bar{p}$ collision happens and where most particles originate. The vertex finder algorithm ZVERTEXFINDER generates a seed list of track vertex candidates with certain quality requirements based on silicon and COT hits. z_0 is the distance from the center of the detector to the intersection of the beamline and the interpolation of the track. Vertices with a z_0 distance smaller than 3 cm are joined and a new weighted z_0 is calculated for the vertex compound. If there are no vertices or vertex compounds with a distance less than 3 cm left, the vertex or vertex compound with the highest transverse energy and CDF quality 12 is chosen as the event vertex z_V . For events, which we select, we require

$$|z_V| < 60 \text{ cm} . \quad (4.7)$$

4.2.2 Tracks

ID Cut	Track
Track $ z_0 $	$\leq 60 \text{ cm}$
Track $ z_0 - z_V $	$\leq 5 \text{ cm}$
p_T	$\geq 5 \text{ GeV}$
NAxialSeg(≥ 5 Hits)	≥ 3
NStereoSeg(≥ 5 Hits)	≥ 3
Fractional Track Isolation	0

Table 4.2: Identification requirements for isolated tracks. In addition we require that the track is not associated to a selected electron or muon.

In this analysis tracks with hits in the Central Outer Tracker are used; if available, hits in the silicon system are matched. The track reconstruction algorithm[39, 40] looks for seeds, which are hits in three neighboring layers, and fits a straight line. Close hits are added, the line fit is adapted and a segment-linking algorithm forms a track from the seeds. Tracks are also fit by the histogram-tracking algorithm. A histogram is filled with the likelihood, that

a track might pass through a hit as a function of the track radius. If a bin content reaches a certain threshold, a track is fit.

Figure 4.4: Distribution of transverse momentum for electrons, muons and isolated tracks in dilepton + track events at generator level for benchmark point BP1. The leptons are ordered by decreasing p_T . A cut of $p_T > 4$ GeV was applied to remove leptons from meson decays.

For the identification of a track we require the conditions listed in Table 4.2, where

Track $|z_0|$ is the distance from the center of the detector to the intersection of the beamline and the interpolation of the track,

Track $|z_0 - z_V|$ is the distance from z_0 to the event vertex z_V .

p_T is the transverse momentum of the track,

NAxialSeg(≥ 5 Hits) and **NStereoSeg**(≥ 5 Hits) are the numbers of axial and stereo segments in the central outer tracker with at least 5 hits,

Fractional Track Isolation is defined as the ratio of the scalar sum of p_T of all tracks in a cone of 0.4 in the (η, ϕ) -plane with $p_T > 0.4$ GeV and p_T of the candidate track. The tracks considered need to satisfy

$$\left| z_0^{\text{surrounding}} - z_0^{\text{candidate}} \right| < 4 \text{ cm}. \quad (4.8)$$

We require a fractional track isolation of 0 which is equivalent to having no tracks passing these requirements in the cone.

By restricting the choice of tracks to tracks from the COT an additional implicit pseudo-rapidity cut $|\eta| < 1.5$ is introduced. The transverse momentum distribution for tracks in signal Monte Carlo can be found in Fig. 4.4.

4.2.3 Electrons

For the reconstruction of electrons (and muons) we follow the standard CDF joint physics definition[41] for most requirements. In the CDF detector a central electron is a COT track that is matched to a deposit in the electromagnetic calorimeter. We identify central tight (TCE) and central loose electrons (LCE), where central refers to $|\eta| < 1.1$ and tight and loose refers to the degree of the identification requirements. Electrons in the forward region of the detector, the so-called Phoenix or plug electrons, are not reconstructed for this analysis. We require the conditions documented in Table 4.3, where

CEM fiduciality is the requirement for the calorimeter deposit to be away from problematic regions of the central electromagnetic calorimeter. The fiducial volume doesn't include tower 9 and the chimney in tower 7, where the cables exit the detector. Additionally a signal in a CES wire and strip cluster is required.

$E_T = E \sin \theta$ **and** $p_T = p \sin \theta$ are the transverse energy measured in the calorimeter and the transverse momentum measured in the tracker.

Had/EM is the ratio of hadronic and electromagnetic energy. It is expected that an electron deposits most of its energy in the electromagnetic calorimeter.

CES χ^2_{strip} is a statistic measure for how similar the CES shower profile is to test beam data.

Isolation energy is the energy in a cone of $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} = 0.4$ around the calorimeter deposit.

Fractional isolation is the ratio of the isolation energy and the energy of the cluster itself.

E/p is the ratio of energy deposit and momentum of the track, which is, due to the small electron mass, usually close to 1.

ID Cut	Central Tight Electron	Central Loose Electron
Fiduciality	CEM	CEM
Track $ z_0 $	$< 60 \text{ cm}$	$< 60 \text{ cm}$
Track $ z_0 - z_V $	$< 5 \text{ cm}$	$< 5 \text{ cm}$
E_T	$\geq 4 \text{ GeV}$	$\geq 4 \text{ GeV}$
p_T	$\geq 4 \text{ GeV}$	$\geq 4 \text{ GeV}$
Had/EM Energy	$< 0.055 + 0.00045 \times E_{EM}/\text{GeV}$	$< 0.055 + 0.00045 \times E_{EM}/\text{GeV}$
NAxialSeg(≥ 5 Hits)	≥ 3	≥ 3
NStereoSeg(≥ 5 Hits)	≥ 2	≥ 2
CES χ_{strip}^2	< 10	< 20
Fractional Isolation	< 0.1 if $E_{EM,T} > 20 \text{ GeV}$	< 0.1
Isolation Energy	$< 2 \text{ GeV}$ if $E_{EM,T} > 20 \text{ GeV}$	-
E/p	< 2 if Track $p_T < 50 \text{ GeV}$	-
Lshr	< 0.2	-
charge $\times \Delta X$	$> -3 \text{ cm}$ and $< 1.5 \text{ cm}$	-
$ \Delta Z $	$< 3 \text{ cm}$	-

Table 4.3: Electron identification requirements for tight central and loose central electrons

Lshr is defined as^[42]

$$\text{Lshr} = 0.14 \times \frac{\sum_i (M_i - P_i)}{\sqrt{(0.14\sqrt{E_{EM}})^2 + \sum_i \Delta P_i^2}}, \quad (4.9)$$

where all numbers are in GeV, i sums over the calorimeter towers adjacent to the seed tower, M_i is the measured energy deposit in tower i , P_i is the predicted energy deposit in tower i based on test beam data, ΔP_i is a measure of the error of P_i and E_{EM} is the total electromagnetic energy in the considered cluster.

Charge $\times \Delta X$ is the charge of the track multiplied by the distance in the (r, ϕ) -plane between the interpolation of the COT track and the nearest CES cluster.

$|\Delta Z|$ is the distance in the (r, z) -plane between the interpolation of the COT track and the nearest CES cluster.

The assignment to the categories is exclusive; a candidate lepton that is able to pass the requirements for TCE and LCE is categorized as a TCE electron.

It can be seen in Fig. 4.5, that for a good signal acceptance, it is crucial to identify leptons with low transverse momentum or energy. For increasing $\tan \beta$ this becomes even more important as the number of τ leptons increases³ and electrons and muons, which are decay products of a τ leptons, are usually softer than electrons or muons, that originate from neutralinos, sleptons or off-shell $W^{\pm*}$ or Z^{0*} bosons. For this reason the requirements on the lepton transverse momentum and energy are significantly lower than the CDF joint physics definition.

4.2.4 Muons

For the identification of muons information from the tracker, the calorimeter and the muon system (for CMUP and CMX muons) is used. The energy deposited in the calorimeter has to be consistent with the signal from a minimum ionizing particle. The CMUP, CMX category is named after the muon systems, where the muon has left a stub; CMIO muons are stubless. For the reconstruction of CMUP or CMX muons a stub in the muon system

³See section 5.1.3 for details.

ID Cut	CMUP, CMX	CMIO
Fiduciality	(CMU and CMP) or CMX	not (CMU and CMP), not CMX
$ \eta $	≤ 1.0	≤ 1.0
BC p_T	$\geq 4 \text{ GeV}$	$\geq 10 \text{ GeV}$
Track $ z_0 $	$\leq 60 \text{ cm}$	$\leq 60 \text{ cm}$
Track $ z_0 - z_V $	$\leq 5 \text{ cm}$	$\leq 5 \text{ cm}$
E_T	$\geq 5 \text{ GeV}$	$\geq 5 \text{ GeV}$
Stub Matching ΔX (CMU, CMP, CMX)	$\leq 7, 5, 6$	-
Track χ^2 (Data)	< 2.3	< 2.3
Corrected d_0 (for Si Hits, for no Si Hits)	$\leq 0.2, 0.02$	$\leq 0.2, 0.02$
NAxialSeg(≥ 5 Hits)	≥ 3	≥ 3
NStereoSeg(≥ 5 Hits)	≥ 2	≥ 3
Had Energy	$\leq 6 \text{ GeV} + \text{sliding}$	$\leq 6 \text{ GeV} + \text{sliding}$
EM Energy	$\leq 2 \text{ GeV} + \text{sliding}$	$\leq 2 \text{ GeV} + \text{sliding}$
EM + Had Energy	$\geq 0.1 \text{ GeV}$	$\geq 0.1 \text{ GeV}$
Fractional Isolation	≤ 0.1 for track $p_T > 20 \text{ GeV}$	≤ 0.1
Isolation Energy	$\leq 2 \text{ GeV}$ for track $p_T < 20 \text{ GeV}$	

Table 4.4: Muon identification requirements for CMUP/CMX and CMIO muons. “+ sliding” stands for the requirements Had Energy $\leq 6 \text{ GeV} + \max(0 \text{ GeV}, 0.0028 \times (p - 100 \text{ GeV}))$ if track $p_T > 20 \text{ GeV}$, Had Energy $< 3.5 + 1/8 \times \text{track } p_T$ if track $p_T \leq 20 \text{ GeV}$ and EM Energy $\leq 2 \text{ GeV} + \max(0 \text{ GeV}, 0.0115 \times (p - 100 \text{ GeV}))$.

Figure 4.5: Distribution of transverse momentum for electrons and muons in trilepton events at generator level for benchmark point BP1. The leptons are ordered by decreasing p_T . A cut at $p_T = 4$ GeV was applied to remove leptons from meson decays.

is used as a seed and the best matching calorimeter deposits and tracks are identified. In addition we pose the requirements listed in Table 4.4, where

η is the pseudorapidity of the muon given by

$$\eta = -\ln \tan \frac{\theta}{2}, \quad (4.10)$$

Fiduciality here refers to the appropriate regions in the CMU, CMP or CMX muon system,

BC p_T is the beam constrained track p_T ,

Stub Matching ΔX is the distance in the (r, ϕ) -plane between the interpolation of the COT track and the muon stub,

Track χ^2 (Data) is a measurement for the agreement of the track and the hits in the COT and reduces the background from poorly reconstructed tracks, primarily from kaons that decay in flight,

Corrected d_0 is the impact parameter of the track, the distance between the beamline and the position of the track's interpolation in the (r, ϕ) -plane.

All other requirements have been explained in section 4.2.3. Similar to the assignment of electron categories the assignment of muon categories is exclusive; a candidate lepton that is

able to pass the requirements for CMUP/CMX and CMIO is categorized as a CMUP/CMX muon.

4.2.5 Jets

Jets are clusters of towers with signals in the hadronic and electromagnetic calorimeters. In this analysis jets were identified with the JETCLU algorithm and a cone radius of $\Delta R = 0.4$ [43]. The algorithm is described below:

1. A list of seed towers with $E_T = E_{em} \sin \theta_{em} + E_{had} \sin \theta_{had} > 1.0 \text{ GeV}$ is created.
2. The highest E_T seed tower (and subsequently all other to that point unused seed towers) are defined as a precluster and seed towers within a cone of

$$\Delta R = \sqrt{\left(\eta_{\text{tower}} - \eta_{\text{precluster}}\right)^2 + \left(\phi_{\text{tower}} - \phi_{\text{precluster}}\right)^2} = 0.4 \quad (4.11)$$

around the precluster are exclusively assigned to the precluster. It has to be noted that η and ϕ of the precluster change when towers are added.

3. Other calorimeter towers within the cone and $E_T > 0.1 \text{ GeV}$ are added.
4. The overlap fraction of preclusters is calculated as the energy of common towers divided by the energy of the smaller cluster. If the overlap fraction is greater than 75% the clusters are merged; otherwise common towers are assigned exclusively to the nearer cluster.
5. Final clusters are regarded as jets.

After clustering the jet energy is corrected to level 5 which includes online/offline calibrations (for example corrections for minimum ionizing particles, level 0), η dependent corrections (level 1), correction for multiple interactions as a function of the number of vertices in the event (level 4) and corrections for non-linearity and energy loss in the uninstrumented regions of the calorimeter (level 5). A systematic error for the jet energy scale is applied according to section 4.6.2. In this analysis we select jets with raw $E_T > 8 \text{ GeV}$, level-5 corrected $E_T > 15 \text{ GeV}$ and EM fraction < 0.9 . Jets are not used as a direct analysis object, but to correct missing transverse energy and to reject events with high hadronic activity or jets that are close to analysis objects.

4.2.6 Identification Scale Factors

If the identification efficiency for leptons is compared in data and in Monte Carlo, it turns out that there are differences. To account for these differences a scale factor for the identification of leptons is introduced. A description of how these scale factors are obtained can be found in [44]. The track identification scale factors are assumed to be 1.

Lepton	E_T range	Scale factor
TCE	≥ 20 GeV	0.979 ± 0.006
	$8 \dots 20$ GeV	0.96 ± 0.02
	$5 \dots 8$ GeV	0.88 ± 0.16
LCE	≥ 20 GeV	$0.964 \times 1.025 \pm 0.03$
	$8 \dots 20$ GeV	$0.968 \times 1.015 \pm 0.03$
	$5 \dots 8$ GeV	0.97 ± 0.10
CMUP	≥ 20 GeV	0.92 ± 0.006
	$8 \dots 20$ GeV	0.90 ± 0.04
	$5 \dots 8$ GeV	0.87 ± 0.04
CMX	≥ 20 GeV	0.97 ± 0.01
	$8 \dots 20$ GeV	0.91 ± 0.04
	$5 \dots 8$ GeV	0.88 ± 0.04
CMIO	≥ 20 GeV	1.0 ± 0.01
	$10 \dots 20$ GeV	1.01 ± 0.057

Table 4.5: Lepton identification scale factors

4.2.7 Missing Transverse Energy

Neutrinos and the lightest neutralino interact with the detector material only via the weak force, so that their energy can not be measured. However they carry away energy and momentum leaving an unbalance. As the Tevatron is a hadron collider the longitudinal energy of the interacting quarks can not be unambiguously determined. It is therefore

necessary to restrict the search for a momentum unbalance to the transverse component. The transverse energy of an event is defined as

$$\vec{E}_T^{\text{raw}} = \sum_{i=1}^{N_{\text{towers}}} E_{\text{tower},i} \sin \theta_i \vec{n}_i, \quad (4.12)$$

where N_{towers} is the number of towers in the calorimeter, $E_{\text{tower},i}$ is the energy deposited in calorimeter tower i , \vec{n}_i is a unit vector pointing from the center of the detector to the center of calorimeter tower i and θ_i is the angle between \vec{n}_i and the beam axis, so that $\sin \theta_i \vec{n}_i$ is the transverse component of \vec{n}_i . The z component of \vec{E}_T^{raw} is set to 0. Missing transverse energy $\vec{\cancel{E}}_T$ can thus be defined by

$$\vec{\cancel{E}}_T^{\text{raw}} = -\vec{E}_T^{\text{raw}}, \quad (4.13)$$

but it is often used as a scalar quantity. Missing E_T is vulnerable towards mismeasurements. Corrections for overlapping jets and tracks, muons, jets and tracks that are not associated to a muon, but have a signal in the muon chambers, are applied to account for mismeasurements.

- If an isolated track that is not coming from a minimum ionizing muon and a jet have a distance $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.4$, the missing E_T is corrected for the energy difference of the jet and the track. If the track E_T is lower than the jet E_T , the track is probably included in the jet; if the jet E_T is lower than the track E_T , the jet E_T is certainly measured too low by mistake.
- For jets with $|\eta| > 2.5$ and $E_T > 15 \text{ GeV}$ the missing E_T is corrected for the difference in raw E_T and level-5 corrected E_T ⁴.
- For selected muons the missing E_T is corrected for the difference between muon track p_T and $E_T = \frac{E_{\text{em}} + E_{\text{had}}}{\cosh \eta}$ as muons are minimum ionizing particles.
- In the dilepton + track channels⁵ missing E_T is corrected for the difference between E_T and track p_T of a track if there is no signal in the muon chamber and $E/p < 1.0$.

The effects of the corrections on the missing E_T distribution can be seen in Fig. 4.6.

⁴ η is calculated assuming $z_0 = 0$.

⁵For details on the definition of analysis channels see Table 4.6.

Figure 4.6: Effects of successively applied corrections to missing E_T for benchmark point BP1 in the $l_t l_t T$ channel at the level of full detector simulation. The histograms for the corrections contain all previous corrections, e.g. the value for \cancel{E}_T corrected for tracks contains all other corrections.

4.2.8 Event Vetoes

We require an event vertex to be selected according to section 4.2.1. Events where no event vertex can be selected are rejected.

Cosmic Ray Veto

Cosmic rays are energetic particles from space that produce pions and kaons when they interact with gas atoms in the earth's atmosphere. Pions and kaons are unstable and can decay into muons. As muons are minimum ionizing particles their interaction with the earth's atmosphere is weak enough, so that the energetic ones are able to reach the earth's surface and can be seen in the CDF detector. When a cosmic muon passes the CDF detector it can be reconstructed as two oppositely charged muons. When going into the detector the muon is travelling in opposite direction to a muon that would come from the interaction point and the muon charge is misidentified.

In this analysis we use the CDF Run II Cosmic Ray Tagger[45] to reject events with cosmic muons. The Cosmic Ray Tagger is rejecting events based on their timing and geometry information as muons from cosmic rays are expected to be out-of-time and back-to-back.

Photon Conversion Veto

The process of a photon decaying into two oppositely charged electrons is called a conversion. In this analysis a pair of electrons having opposite charge may be rejected if $\Delta \cot \theta$ and the minimal separation of the associated tracks are consistent with a conversion. The photon conversion removal efficiency is different for data and Monte Carlo; a scale factor is applied to account for different conversion removal efficiencies[46].

Separation Veto

To avoid effects from not uniquely reconstructed analysis objects, we require a separation in the (η, ϕ) -plane of $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} > 0.4$ between

- lepton - lepton
- lepton - track
- lepton - jet and
- track - jet pairs.

In addition we reject events where

- the missing E_T and any jet with $E_T > 10$ GeV are azimuthally separated by less than $\Delta\phi = 0.35$. Previous studies in jet20 data[47] have shown a strong correlation of the difference in azimuthal separation and mismeasurement of missing E_T ,
- the missing E_T and the leading or next-to-leading lepton are azimuthally separated by less than $\Delta\phi = 0.17$. Previous studies have shown that this requirement rejects mismeasurement of missing E_T in Drell Yan events.

4.3 Definition of the Analysis Channels

⁷Exclusive here refers to the exclusivity of the trilepton and dilepton channels within each category; for example the events of the trilepton channel $l_t l_t l_t$ are fully included in the dilepton channel $l_t l_t$, but the trilepton channels $l_t l_t l_t$ and $l_t l_t l_t$ are exclusive.

Channel	Selection	E_T^i/GeV , $i = 1, 2(, 3)$
Trilepton channels		
$l_t l_t l_t$	3 tight leptons or 2 tight leptons + 1 LCE	15, 5, 5(8 if LCE)
$l_t l_t l_l$	2 tight leptons and 1 CMIO	15, 5, 10
$l_t l_l l_l$	1 tight lepton and 2 loose leptons	20, 8, 5(10 if CMIO)
Dilepton + track channels		
$l_t l_t T$	2 tight leptons and 1 isolated track	15, 5, 5
$l_t l_l T$	1 tight and 1 loose lepton and 1 isolated track	20, 8(10 if CMIO), 5

Dilepton channels		
$l_t l_t$	2 tight leptons	15, 5
$l_t l_l$	1 tight lepton and 1 loose lepton	20, 8(10 if CMIO)

Table 4.6: Definition of exclusive⁷ trilepton and dilepton analysis channels. Dilepton analysis channels are only considered as control regions.

Based on section 4.2 we can reconstruct different analysis objects. As the signature of the leptonic $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ decay is three leptons and missing transverse energy we define our analysis channels based on the content of main analysis objects, where main analysis objects are TCE and LCE electrons, CMUP/CMX and CMIO muons and isolated tracks. In general the signal to background ratio of events is strongly dependent on the analysis object content, e.g. the signal to background ratio of an event with three TCE electrons is higher than the same ratio for an event with 1 TCE and 2 LCE leptons. The sensitivity of any physics analysis is highly dependent on the signal to background ratio. Assigning the events to different analysis channels based on the signal to background ratio results in a higher sensitivity than having only one channel. Tight leptons are defined as TCE electrons or CMUP/CMX muons; loose leptons are LCE electrons or CMIO muons as these have similar signal to background ratios. Analysis channels are then defined as documented in Table 4.6. To preserve the ability of a simple unification of the results in the five analysis channels into a single result, the analysis channels are defined exclusively: Every event is assigned to the analysis channel with highest signal to background ratio to maximize sensitivity. The

signal to background fraction of the analysis channels is given in Table 4.10. In addition we require for all analysis channels, that

$$\left| \sum_{i=1}^3 q_i \right| = 1, \quad (4.14)$$

where q_i is the charge of the selected lepton or isolated track i , $i = 1, 2, 3$. Even though the signature requires that, out of the three selected leptons, there are always two leptons of a kind (e^+e^- , $\mu^+\mu^-$, $\tau^+\tau^-$), we have no requirement on the lepton flavor. Otherwise, as τ leptons are not identified directly, the case

$$\tilde{\chi}_1^+ \tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \mu^- \tilde{\chi}_1^0 \tau^+ \tau^- \rightarrow \tilde{\chi}_1^0 \mu^- \tilde{\chi}_1^0 e^+ \bar{\nu}_e \nu_\tau \pi^- \nu_\tau \quad (4.15)$$

leads to a final state that would not have passed such a lepton flavor requirement.

4.4 Standard Model and Non-physics Background

The possible background processes for the trilepton and missing E_T signature is dependent on the nature of the analysis objects and thus the analysis channel: the background of the dilepton+track channels is fundamentally different from the background of the trilepton channels.

4.4.1 Background in the Trilepton Channels

The major backgrounds for channels with three leptons are

- three genuine leptons from
 1. WZ/γ^*
 2. $Z/\gamma^*Z/\gamma^*$
 3. $t\bar{t}$ with a subsequent semileptonic B decay
- two genuine leptons and a lepton from a photon conversion from
 1. WW and a photon conversion
 2. Drell Yan and a photon conversion

- two genuine leptons and a third lepton from the underlying event (“fake”)⁸

The background contribution from processes with three genuine leptons including the processes where one lepton comes from a photon conversion is estimated in Monte Carlo. We weight Monte Carlo events by their respective trigger efficiencies and lepton identification scale factors. The fake contribution is fully estimated in data. For details on the estimation method, see section 4.4.4. As the probability of obtaining a faked lepton is relatively small, the contribution of events with two or three objects being faked is negligible[48].

4.4.2 Background in the Dilepton + Track Channels

The major backgrounds for channels with two genuine leptons and one isolated track is

- two genuine leptons and one isolated track from a not fully reconstructed lepton from
 1. WZ/γ^*
 2. WW and a photon conversion
 3. $Z/\gamma^*Z/\gamma^*$
 4. $t\bar{t}$ with a subsequent semileptonic B decay
 5. Drell Yan and a photon conversion
- one isolated track from the underlying event or a jet, where one charged particle showers outside the core of the jet, and two genuine leptons from
 1. WZ/γ^*
 2. WW
 3. $Z/\gamma^*Z/\gamma^*$
 4. $t\bar{t}$
 5. Drell Yan
- two genuine leptons and a third lepton from the underlying event (“fake”)⁹

⁸Background from processes with one faked lepton is estimated independently of the production process for the two real leptons. However, the major contribution is from Drell Yan.

⁹Backgrounds from processes with one faked lepton are estimated independently of the production process for the two real leptons. However, the major contribution is Drell Yan and $W + \text{jets}$, where one lepton comes from the W , one lepton is faked by a jet and another jet is identified as an isolated track.

4.4.3 The Isolated Track Rate

The isolated track rate[49] is a measure for the probability of getting an additional track from the underlying event. We measure the isolated track rate in $Z \rightarrow e^+e^-$ and $Z \rightarrow \mu^+\mu^-$ data from the high p_T electron and muon triggers as a function of all tracks of a certain quality in the event.

We select $Z \rightarrow ee$ and $Z \rightarrow \mu\mu$ events by requiring two tight electrons or muons with an invariant mass $|m_{ll} - 91.2 \text{ GeV}| < 15 \text{ GeV}$. In addition we require $\cancel{E}_T < 10 \text{ GeV}$ to remove background with intrinsic \cancel{E}_T (WZ , $t\bar{t}$). The remaining background is below 1%[50]. The ratio of the number of events with at least one isolated track and the number of all events with a certain number of tracks (excluding the two tracks forming the Z mass) is defined as the isolated track rate. We reconstruct tracks based on the requirements in Table 4.2, where the isolation requirement is applied to isolated tracks only.

Figure 4.7: Measurement of the isolated track rate in Z events

Figure 4.7 shows the results of this measurement. For $N_{\text{Tracks}} > 2$ we assume that the isolated track rate is constant and fit a function of the form $\text{ITR}(N_{\text{Tracks}}) = p_0$. We then obtain the isolated track rate

$$\text{ITR}(N_{\text{Tracks}}) = \begin{cases} 0.075 \pm 0.005 & \text{for } N_{\text{Tracks}} = 1 \\ 0.037 \pm 0.006 & \text{for } N_{\text{Tracks}} = 2 \\ 0.024 \pm 0.007 & \text{for } N_{\text{Tracks}} > 2 \end{cases} . \quad (4.16)$$

The isolated track rate is applied to events in Monte Carlo if there are two identified leptons and every track is matched to one of the generator-level leptons. Together with the trigger efficiency and the lepton ID scale factor the isolated track rate forms the event weight $\varepsilon_{\text{dilep}}$. As the isolated track rate does not include any information about of the additional track (e.g. angles to other tracks), it is not possible to apply the usual cuts to this type of events. We assume that the ratio of events that pass the cut to all events with two genuine lepton and one isolated track from the underlying event is equal to the equivalent ratio for events with two leptons and a track, that is not from the underlying event. This ratio is denoted by $N_{\text{dilep+track}}^{\text{cut}}/N_{\text{dilep+track}}^{\text{base}}$, where $N_{\text{dilep+track}}^{\text{base}}$ is the number of events before and $N_{\text{dilep+track}}^{\text{cut}}$ the number of events after cuts. If we denote the number of dilepton events that are missing a track by N_{dilep} , the average event weight for dilepton + track events by $\varepsilon_{\text{dilep+track}}^{\text{cut}}$ and the total number of events by N_{gen} , the overall event acceptance is

$$A = \frac{N_{\text{dilep+track}}^{\text{cut}} \varepsilon_{\text{dilep+track}}^{\text{cut}} + N_{\text{dilep+track}}^{\text{cut}}/N_{\text{dilep+track}}^{\text{base}} N_{\text{dilep}} \varepsilon_{\text{dilep}}}{N_{\text{gen}}} . \quad (4.17)$$

4.4.4 The Fake Rate

The expected number of events, where two leptons come from a physics process and third lepton from underlying event, is estimated with the so-called fake rate[51]. The fake rate is a measure for the probability of a jet being reconstructed as an electron or a track being reconstructed as a muon. In addition the fake rate includes real leptons within jets from processes such as a semileptonic B decay.

In jet-triggered samples jets, isolated tracks, electrons and muons are reconstructed. For the electron fake rate we count the number of jets and the number of reconstructed leptons, which are within $\Delta R = \sqrt{\Delta\eta^2 + \Delta\phi^2} < 0.4$ of any reconstructed jet, as a function of the

Figure 4.8: Fake rates for TCE, LCE, CMUP, CMX and CMIO leptons. We fit an exponential added to a constant to the fake rates for TCE, LCE and CMIO and first order polynomials to the fake rates for CMUP and CMX. The dashed lines show the 50% systematic error.

jet's E_T . The electron fake rate is defined as the ratio of counted leptons and the number of all jets as a function of jet E_T . The muon fake rate is determined in a similar way; unlike for electrons where jets have the ability to fake, for muons isolated tracks have the ability to fake. The fake rate is defined accordingly. A constant and an exponential of the form

$$f(x) = p_0 + \exp(p_1 \times E_T + p_2) \quad (4.18)$$

are fit to the fake rates of TCE, LCE and CMIO leptons independently. To CMUP and CMX muon fake rates we fit a first order polynomial of the form

$$f(x) = p_0 + p_1 x. \quad (4.19)$$

The results are shown in Fig. 4.8.

The fake rates are then applied to dilepton events in data where a fakeable object exists. According to the measurement of the fake rate a fakeable object is a jet for electrons and an isolated track for muons. Similar to the application of the isolated track rate the fake rate is used as a component of the event weight.

4.5 Control and Signal Regions

This analysis is set up as an unbiased counting experiment. We define signal and control regions. Before the data in the signal region is examined, we verify our background predictions in the control regions.

4.5.1 Definition

In order to check the estimation methods several control regions are defined. The signal signature is expected to have high \cancel{E}_T , so that we demand $\cancel{E}_T > 15 \text{ GeV}$ for the signal region. In addition we define our signal region outside a window of 15 GeV around the Z mass, where $m_{OS}^1 \in [76 \text{ GeV}, 106 \text{ GeV}]$ and m_{OS}^1 is the higher of the two invariant masses that can be formed from the three analysis objects. In this region we expect the observed events to be dominated by background from Drell Yan. We use the regions where $m_{OS}^1 \in [76 \text{ GeV}, 106 \text{ GeV}]$ or $\cancel{E}_T < 15 \text{ GeV}$ as control regions. The control regions are further split into the analysis channels of Table 4.6. The control region where $m_{OS}^1 \in [76 \text{ GeV}, 106 \text{ GeV}]$

Figure 4.9: Illustration to the definition of signal and control regions. !Zhi is the signal region for trilepton events; for dilepton events !Zhi is a control region. m_{OS}^1 is the higher of the two invariant masses that can be calculated from three analysis objects

is used to check the estimations for Drell Yan; the region where $\cancel{E}_T < 10 \text{ GeV}$ is used to check low mass Drell Yan. Compared to the number of events with two leptons the number of events with three leptons is relatively low. To check the predictions in regions with high statistics we use events with two leptons as control regions. We split them into channels with two tight leptons and one tight and one loose lepton. The control region with two leptons and high missing E_T can be used to test the predictions for $t\bar{t}$. Additionally we use control regions based on the lepton flavor of the final states. The naming scheme and the exact definition of control and signal regions can be found in Table 4.7.

4.5.2 Background Estimation

We estimate the Standard Model and non-physics background with exception of the fake contribution in the Monte Carlo samples listed in Table 3.1. The predictions can be found in appendix A. In Figs. 4.10 and 4.11 the ratio of the difference of observed and expected and the expected number of event for the control regions defined in Table 4.7 is plotted. If the predictions are consistent with the observations, the plotted ratio should agree with 0 within its limits.

Region	Definition	
Trilepton Control Regions		
Signal	$\cancel{E}_T > 15 \text{ GeV}$	$m_{OS}^1 \notin [76 \text{ GeV}, 106 \text{ GeV}]$
Zlo	$\cancel{E}_T < 10 \text{ GeV}$	$m_{OS}^1 \in [76 \text{ GeV}, 106 \text{ GeV}]$
!Zlo	$\cancel{E}_T < 10 \text{ GeV}$	$m_{OS}^1 \notin [76 \text{ GeV}, 106 \text{ GeV}]$
!Zhi	$\cancel{E}_T > 15 \text{ GeV}$	$m_{OS}^1 \notin [76 \text{ GeV}, 106 \text{ GeV}]$
Dilepton Control Regions		
Z		$m_{ll} \in [76 \text{ GeV}, 106 \text{ GeV}]$
Zlo	$\cancel{E}_T < 10 \text{ GeV}$	$m_{ll} \in [76 \text{ GeV}, 106 \text{ GeV}]$
Zhi	$\cancel{E}_T > 15 \text{ GeV}$	$m_{ll} \in [76 \text{ GeV}, 106 \text{ GeV}]$
!Z		$m_{ll} \notin [76 \text{ GeV}, 106 \text{ GeV}]$
!Zlo	$\cancel{E}_T < 10 \text{ GeV}$	$m_{ll} \notin [76 \text{ GeV}, 106 \text{ GeV}]$
!Zhi	$\cancel{E}_T > 15 \text{ GeV}$	$m_{ll} \notin [76 \text{ GeV}, 106 \text{ GeV}]$
loMet	$\cancel{E}_T < 10 \text{ GeV}$	

Table 4.7: Definition of control and signal regions. For the trilepton control and signal regions, additionally we require $\left| \sum_{i=1}^3 q_i \right| = 1$, where q_i is the charge of analysis object i.

Figure 4.10: Comparison of expected and observed number of events for the dilepton control regions

Figure 4.11: Comparison of expected and observed number of events for the tripleton control regions

Figure 4.12: Summary of expected and observed number of events in all control regions. To check the number of events in the individual control regions for gaussian distribution with $\mu = \text{Exp}$ and $\sigma^2 = \text{Exp}$ we fit a function of the form $C \cdot \mathcal{N}(\mu, \sigma^2)$, where μ , σ^2 and C are the fit parameters.

Following the law of rare events we assume that the numbers of observed events follow a Poisson inspired normal distributions $\mathcal{N}(\text{Exp}, \text{Exp})$ with a density of the form

$$f(x) = \frac{1}{\sqrt{2\pi\text{Exp}}} \exp\left(-\frac{1}{2} \frac{(x - \text{Exp})^2}{\text{Exp}}\right), \quad (4.20)$$

where Exp is the number of expected events. As the mean $\mu = \text{Exp}$ and the variance $\sigma^2 = \text{Exp}$ is different for every analysis channels, we plot $(\text{Obs} - \text{Exp})/\sqrt{\text{Exp}}$, where Obs denotes the number of observed events in data, in a histogram in Fig. 4.12. Assuming the expected number of events is in fact a good background estimation, the histogram should follow a $\mathcal{N}(0, 1)$ distribution. We check this by fitting the appropriate density function with a normalization factor to account for the fact, that the histogram is not normalized and obtain

$$\mu_{\text{fit}} = -0.16 \pm 0.18, \quad (4.21)$$

$$\sigma_{\text{fit}} = 0.78 \pm 0.23, \quad (4.22)$$

which is consistent with the assumption of a $\mathcal{N}(0, 1)$ distribution.

In addition to the comparison of expected and observed number of events we check distributions of $p_T^1, p_T^2, E_T^1, E_T^2, \Delta\phi, m_{ll}, \cancel{E}_T, N_{\text{jets}}, N_{\text{tracks}}$ in each dilepton control region split into the analysis channels $l_t l_t$ and $l_i l_i$. In the trilepton control regions we check the distribution of $p_T^1, p_T^2, p_T^3, E_T^1, E_T^2, E_T^3, \Delta\phi_{12}, \Delta\phi_{13}, \Delta\phi_{23}, m_T^1, m_T^2, m_T^3, m_{OS}^1, m_{OS}^2, \cancel{E}_T, N_{\text{jets}}$ in each analysis channel. A selection of control region plots can be seen in Figs. 4.13 to 4.16; a more complete set of control region plots can be found in [52].

4.6 Predictions and Results for the Signal Region

4.6.1 Signal Optimization

For the signal region we define additional cuts to optimize the analysis channels for a better signal to background ratio. In the following we list the optimization cuts and the backgrounds which are most affected by the cut:

- $\cancel{E}_T \geq 20 \text{ GeV}$ to remove Drell Yan which has no intrinsic \cancel{E}_T

Figure 4.13: Invariant mass of the two leptons in the $l_t l_t$ analysis channel of the loMet dilepton control region

Figure 4.14: Invariant mass of the two leptons in the $l_t l_t T$ analysis channel of the loMet trilepton control region

Figure 4.15: Missing transverse energy of events in the $l_t l_t$ analysis channel of the Z dilepton control region

Figure 4.16: Missing transverse energy of events in the $l_t l_t T$ analysis channel of the Z trilepton control region

- $\Delta\phi_{OS}^i \leq \begin{cases} 2.9 & \text{for the dilepton + track channels} \\ 2.8 & \text{for the trilepton channel} \end{cases}$
and $i = 1, 2$ to remove Drell Yan, where the leptons have the tendency to be back-to-back.
- $m_{OS}^i \notin [76 \text{ GeV}, 106 \text{ GeV}]$ for $i = 1, 2$ to remove on-shell Drell Yan and diboson background
- $N_{\text{jets}} < 2$ and $\sum_{\text{jets}} E_{T,i} \leq 80 \text{ GeV}$, where the sum goes over jets with $E_T^{\text{jet}} > 10 \text{ GeV}$, to remove QCD, especially $t\bar{t}$, background where hadronic activity is expected. The leptonic decay of chargino and neutralino does not produce hard jets.

The background estimation for the signal region based on Monte Carlo (data for the fake category) and optimized cuts for the supersymmetric signal can be found in Table 4.8.

Background Process	Channels				
	$l_t l_t l_t$	$l_t l_t l_l$	$l_t l_l l_l$	$l_t l_t T$	$l_t l_l T$
$Z \rightarrow ee$	0.03	0.00	0.00	0.81	0.73
$Z \rightarrow \mu\mu$	0.02	0.01	0.00	0.00	0.30

Table 4.8: Number of expected signal and background events for $\int \mathcal{L} dt = 2.0 \text{ fb}^{-1}$ of data. Uncertainties are statistical and partial systematics. The boson background processes include off-shell bosons.

4.6.2 Systematic Error

The systematic errors used for this analysis are listed in Table 4.9, where

Figure 4.17: Signal and background N-1 plots for the \cancel{E}_T , $\Delta\phi_{OS}^i$, m_{OS}^i and the N_{jets} cuts in the analysis channel $l_t l_t T$ (for the $\sum E_{T,i}$ cut in the channel $l_t l_t l_t$). The backgrounds are stacked. We apply all cuts except the cut on the quantity plotted; N_{jets} and $\sum E_{T,i}$ are highly correlated and we plot N-2 plots, where the cuts of both quantities are not applied.

Source	Channels					Signal at BP1
	$l_t l_t l_t$	$l_t l_t l_l$	$l_t l_l l_l$	$l_t l_t T$	$l_t l_l T$	
ID	2.3	2.5	2.2	1.8	1.8	4
Trig	0.3	0.3	0.3	0.2	0.2	0.5
JES	1.5	1.7	3.5	3.9	5.2	0.5
X-sec	5.0	5.9	5.0	2.3	2.4	10
PDF	1.4	1.6	1.3	1.5	1.5	2

Conv	2.2	2.1	1.8	-	-	-
ITR (nom)	-	-	-	5.8	8.6	-
ITR (alt)	-	-	-	6.0	10.5	-
Fake	12.2	8	10.7	11.6	9.0	-

Table 4.9: Systematic error broken down by source and channel in percentage. A universal 6% uncertainty on the luminosity is not included.

ID is the error of the lepton identification scale factors described in the appropriate CDF notes.

Trig is the error of the trigger efficiencies[25].

JES is the error on the Jet Energy Scale. The jet energies are fluctuated up and down by one standard deviation and the difference in acceptance from the nominal is evaluated. In cases where the statistics preclude this type of estimation we use a signal-like selection (two lepton, $\cancel{E}_T > 20$ GeV, $\sum_{\text{jets}} E_{T,i} < 80$ GeV, $N_{\text{jets}} < 2$ and $\Delta\phi_{12} < 2.9$) and get the difference from the nominal.

X-sec is the error on the cross section of the background processes. For diboson processes we use the error from the CDF WZ search[53]; for $t\bar{t}$ we use the error from the top mass measurement[54].

PDF is the error of the Parton Distribution Function. We use the errors quoted by [53, 54].

ISR/FSR is the error due to turning on Initial State (ISR) and Final State Radiation (FSR). We use the measurements from a previous round of this analysis.

Conv is the systematic error on the conversion scale factor. The systematic error from [46] is applied to the backgrounds in trilepton channels where the third lepton is expected to come from a photon conversion, e.g. $Z\gamma \rightarrow ee\gamma$.

ITR (nom) is the systematic on the isolated track rate as described in section 4.4.3.

ITR (alt) is the difference between the ITR parameterized as a function of number of tracks and the ITR parameterized as a function of $\sum_{\text{jet}} E_{T,i}$ where the sum goes over all jets with $E_T^{\text{corr}} > 10 \text{ GeV}$.

Fake is the systematic error on the fake measurement which is taken to be 50%.

Table 4.10: Final number of expected signal and background events in the different analysis channels together with the observed number of events in data. The signal predictions are for benchmark point BP1.

Table 4.10 shows the observed number of events in the signal region in comparison with the expected number based on estimations in Monte Carlo and data. The observed number of events shows no significant excess over the expected number of events in the sum of all channels as well as in every individual channel. A summary of the characteristics of the observed events can be found in Table 4.11. The number of events at the mSUGRA benchmark point BP1 is significantly higher than the expected background. This shows that the analysis is sensitive to mSUGRA. A more detailed analysis of the sensitivity can be found in section 5.

Table 4.11: Characteristics of the observed events. E_T^i , $i = 1, 2, 3$ refers to transverse energy for electrons and transverse momentum for muons and tracks; M_{OS}^i , $i = 1, 2$ are the invariant masses of the two oppositely charged lepton combinations. All numbers are in GeV.

Chapter 5

Interpretation of the Results in the mSUGRA Model

In the following a systematic application of the results of the analysis to the supersymmetric model mSUGRA (minimal supergravity grand unification) is tried. It was chosen to evaluate the results of this analysis in mSUGRA as this model is widely accepted as a benchmark for supersymmetry searches[55, 56]. As discussed in section 2.2.4 mSUGRA has four undetermined scalar parameters and one undetermined sign:

- m_0 , the common scalar mass at the GUT scale,
- $m_{1/2}$, the common gaugino mass at the GUT scale,
- $\tan \beta$, the ratio of the vacuum expectation values of the two Higgs doublets,
- A_0 , the common trilinear coupling constant at the GUT scale,
- $\text{sgn}\mu$, the sign of μ , where μ is the Higgs mixing parameter.

Based on different phenomenology classes a set of three benchmark points is defined in Table 5.1. Benchmark point BP1 was used to evaluate the analysis in section 4.

The ability of this analysis to exclude a distinct set of parameters depends on several factors, among which the most important are:

- Kinematics of the event. As described in section 4.3 the most important cuts for the analysis are minimum transverse momentum requirements for the three leptons (two leptons and one track), a minimum missing transverse energy requirement and the requirement that the invariant mass of a pair of oppositely charged leptons has to be outside a certain interval around the mass of the Z^0 boson. The set of mSUGRA parameters can have an important effect on the transverse momentum of the leptons.

	BP1	BP2	BP3
$m_0 / \text{GeV}/c^2$	60	140	110
$m_{1/2} / \text{GeV}/c^2$	190	190	190
$\tan \beta$	3	3	3
A_0 / GeV	0	0	0
$\text{sgn}\mu$	1	1	-1
$m(\tilde{\chi}_1^0) / \text{GeV}/c^2$	67.8	68.4	77.9
$m(\tilde{\chi}_2^0) / \text{GeV}/c^2$	124.4	125.7	152.3
$m(\tilde{\chi}_1^\pm) / \text{GeV}/c^2$	121.9	123.3	152.7
$m(\tilde{e}_R^\pm) = m(\tilde{\mu}_R^\pm) / \text{GeV}/c^2$	99.8	161.1	135.9
$m(\tilde{\tau}_1^\pm) / \text{GeV}/c^2$	99.7	160.6	135.9
$m(\tilde{\nu}_e) = m(\tilde{\nu}_\mu) / \text{GeV}/c^2$	129.9	180.7	159.0
$m(\tilde{\nu}_\tau) / \text{GeV}/c^2$	128.8	180.1	158.2

Table 5.1: Definition of the mSUGRA benchmark points and selected masses

- Cross section for the associated production of a chargino-neutralino pair in a $p\bar{p}$ collision $\sigma(\tilde{\chi}_2^0 \tilde{\chi}_1^\pm)$
- Branching ratio of chargino and neutralino into 3 leptons $\text{BR}(\tilde{\chi}_2^0 \tilde{\chi}_1^\pm \rightarrow 3 \text{ leptons})$
- the ratio of the number of events in a channel with three leptons and the number of events in a channel with two leptons and a track; a good quantity to study this ratio is the mean number of τ leptons per event¹ as signal tracks dominantly come from hadronic τ decays².

¹See appendix C for details.

²The single-prong branching fraction for the τ lepton is 85.33%, among which 17.36% is the decay to $\mu\bar{\nu}_\mu\nu_\tau$ and 17.84% is the decay to $e\bar{\nu}_e\nu_\tau$ [1].

5.1 Effects of the mSUGRA Parameters

In the following we investigate the effect of a change of the mSUGRA parameters. We start at benchmark point BP1 with $m_0 = 60 \text{ GeV}/c^2$, $m_{1/2} = 190 \text{ GeV}/c^2$, $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$ and vary one parameter at a time. For $\mu < 0$ we start at BP3 $m_0 = 110 \text{ GeV}/c^2$, $m_{1/2} = 190 \text{ GeV}/c^2$, $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$ to maximize the sensitivity of the analysis. The mass of the important supersymmetric particles, the branching ratio of the different decay channels, the branching ratio into three leptons split into final states with 0,1,2 or 3 τ leptons and the cross section for chargino-neutralino production are shown.

5.1.1 The Common Scalar Mass m_0

Figure 5.1: Mass of the relevant supersymmetric particles as a function of m_0 at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). Benchmark point BP1 is at $m_0 = 60 \text{ GeV}/c^2$ for $\mu > 0$, benchmark point BP2 is at $m_0 = 140 \text{ GeV}/c^2$ for $\mu > 0$ and benchmark point BP3 is at $m_0 = 110 \text{ GeV}/c^2$ for $\mu < 0$.

It can be seen in Fig. 5.1, that the mass of the neutralino and chargino is almost independent of m_0 , while the mass of the charged sleptons and the sneutrinos has a dependence on m_0 . As long as the mass of the sleptons is lower than the mass of the decaying neutralino and chargino a sequential two-body decay via on-shell sleptons

$$\tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^\pm \nu \rightarrow \tilde{\chi}_1^0 l^\pm \nu, \quad \tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^-, \quad (5.1)$$

where $\tilde{l}_R^\pm = \tilde{e}_R^\pm, \tilde{\mu}_R^\pm, \tilde{\tau}_1^\pm$, is possible and dominant (compare Figs. 5.1, 5.2 and 5.3). The decay via off-shell $W^{\pm*}$ or Z^{0*} boson

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \tilde{\chi}_1^0 l^\pm \nu, \quad \tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \tilde{\chi}_1^0 l^+ l^- \quad (5.2)$$

is dominant for $m(\tilde{l}_R^\pm) \gg m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0)$. In the intermediate region the decay channel via off-shell slepton has a non-negligible contribution.

The decay process has important effects on the transverse momentum of the leptons and the number of τ leptons in the event. In Figs. 5.2 and 5.3 it can be seen that the chargino dominantly decays into a stau slepton, if this decay is kinematically allowed and the decay into sneutrinos is kinematically not allowed. The reason is that the decay via on-shell particles is preferred over a decay via off-shell particles. The chargino is a mixture that has Higgsino and Wino components. For the lighter chargino the Wino component is dominant in the parameter regime considered. For the charged Wino no coupling to right-handed sleptons exists³. As the selectron and smuon have very low mixing between left- and right-handed form and the lighter stau has a significant left-handed component the charged Wino component of the lighter chargino prefers the decay into a stau. The Higgsino component has a Yukawa coupling to sleptons. In the approximation of Eqn. 2.20 the Higgsino component couples only to the stau. As both chargino components have a negligible coupling to the selectron and smuon, the chargino decay into selectron and smuon is negligible and in the region where the decay is kinematically allowed, the chargino decays mostly into a stau. For the next-to-lightest neutralino the Bino component couples to the selectron and the smuon and the decay is possible. However the decay into a stau slepton is enhanced as the Bino, Wino and Higgsino components of the neutralino couple to the stau.

At benchmark point BP1 the branching ratios of the major decay channels are given in Table 5.3. Benchmark point BP2 is in a region, where the decay via an on-shell slepton is kinematically forbidden. The decay of the chargino is via an off-shell $W^{\pm*}$ boson and the decay channels with final states $\tilde{\chi}_1^0 e \nu_e$, $\tilde{\chi}_1^0 \mu \nu_\mu$ and $\tilde{\chi}_1^0 \tau \nu_\tau$ have approximately the same branching ratio. The masses and branching ratios for the point BP2 can be found in the Tables 5.4 and 5.5. Obviously the preferred decay channel has an effect on the number of τ leptons in an event and for this reason also the number of events in the dilepton + track channel. The relevant quantities are the branching ratios of chargino and neutralino into three leptons with $i = 0, 1, 2, 3$ τ leptons, which can be seen in Fig. 5.4. In a region, where

³See Fig. 2.2 for the relevant couplings of the chargino and neutralino components.

the decay via an on-shell stau slepton is kinematically allowed, almost all events have either one or three τ leptons as decay products of the chargino and the neutralino.

It can be seen in Fig. 5.1 that the masses of $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ have a small dependence on m_0 . As a result the dependence of the cross section for their production on m_0 can be neglected. For Fig. 5.5 the cross section for the production of associated $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ in $p\bar{p}$ $\sqrt{s} = 1.96$ TeV collisions at the Tevatron was calculated with PROSPINO 2.0[35]⁴. The low dependence on m_0 can be seen.

Figure 5.2: Branching ratios for the decay of chargino and neutralino as a function of m_0 at benchmark point BP1 with $\mu > 0$. Benchmark point BP1 is at $m_0 = 60$ GeV/ c^2 ; benchmark point BP2 is at $m_0 = 140$ GeV/ c^2 .

Figure 5.3: Branching ratios for the decay of chargino and neutralino as a function of m_0 at benchmark point BP3 with $\mu < 0$. Benchmark point BP3 is at $m_0 = 110$ GeV/ c^2 .

⁴The particle spectrum used was produced with ISAJET 7.75[33].

Particle	Mass
$\tilde{\chi}_2^0$	124.4 GeV/c ²
$\tilde{\chi}_1^\pm$	121.9 GeV/c ²
\tilde{e}_R	99.8 GeV/c ²

Branching ratio into 3 leptons for $\mu > 0$

Branching ratio into 3 leptons for $\mu < 0$

Figure 5.4: Branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons split into final states with 0, 1, 2 or 3 τ leptons as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). Benchmark point BP1 is at $m_0 = 60$ GeV/c² for $\mu > 0$, benchmark point BP2 is at $m_0 = 140$ GeV/c² for $\mu > 0$ and benchmark point BP3 is at $m_0 = 110$ GeV/c² for $\mu < 0$.

Figure 5.5: Cross section for the production of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ in $p\bar{p}$ collisions at the Tevatron as a function of m_0 at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). Benchmark point BP1 is at $m_0 = 60 \text{ GeV}/c^2$ for $\mu > 0$, benchmark point BP2 is at $m_0 = 140 \text{ GeV}/c^2$ for $\mu > 0$ and benchmark point BP3 is at $m_0 = 110 \text{ GeV}/c^2$ for $\mu < 0$.

5.1.2 The Common Gaugino Mass $m_{1/2}$

The mSUGRA parameter $m_{1/2}$ is important for the masses of the relevant particles (and thus the cross section for their production); all relevant particle masses have a strong dependence on $m_{1/2}$. However, Fig. 5.6 shows, that sleptons and charginos or neutralinos show a

Figure 5.6: Mass of the relevant supersymmetric particles as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $m_{1/2} = 190 \text{ GeV}/c^2$ for $\mu > 0$ and $\mu < 0$ respectively.

different dependence on $m_{1/2}$ and for rising values of $m_{1/2}$ the following decay channels are possible:

1. The decay via off-shell particles is always possible, but it is suppressed as long as decay channels via on-shell particles are open. The decay via off-shell particles is mostly a decay via off-shell $W^{\pm*}$ or Z^{0*} boson, where quarks dominate the final state, whereas in the decay via off-shell sleptons leptons and neutrinos are dominant in the final state. In the region, where $m(\tilde{l}_R^{\pm}) \approx m(\tilde{\chi}_2^0)$ the decay via off-shell sleptons is dominant for a small $m_{1/2}$ range.

$$\tilde{\chi}_1^{\pm} \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \begin{cases} \tilde{\chi}_1^0 l^{\pm} \nu_l \\ \tilde{\chi}_1^0 q_1 \bar{q}_2 \end{cases}, \quad \tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \begin{cases} \tilde{\chi}_1^0 l^+ l^- \\ \tilde{\chi}_1^0 q \bar{q} \\ \tilde{\chi}_1^0 \nu \bar{\nu} \end{cases} \quad (5.3)$$

$$\tilde{\chi}_1^{\pm} \rightarrow \tilde{l}_R^{\pm*} \nu_l \rightarrow \tilde{\chi}_2^0 l^{\pm} \nu_l, \quad \tilde{\chi}_2^0 \rightarrow \tilde{l}_R^{\pm*} l^{\mp} \rightarrow \tilde{\chi}_2^0 l^+ l^- \quad (5.4)$$

2. If the slepton mass is lower than the mass of the chargino and neutralino, the decay via an on-shell right-handed slepton is possible and, as long as no other decay via on-shell particles is allowed, this decay is dominant.

$$\tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^\pm \nu_l \quad , \quad \tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp \quad (5.5)$$

3. If the sneutrino mass is lower than the mass of the chargino and the neutralino, the decay

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\nu}_l l^\pm \quad , \quad \tilde{\chi}_2^0 \rightarrow \tilde{\nu}_l \nu_l \quad (5.6)$$

is possible. In the decay of the neutralino via an off-shell sneutrino finally an LSP and two neutrinos are in the final state. As neutrinos are visible only via missing transverse energy in the detector, it is hard to see such a decay. The tripleton analysis is not sensitive to this decay.

4. If the mass of the left-handed sleptons is lower than the mass of the chargino and neutralino, the decay

$$\tilde{\chi}_1^\pm \rightarrow \tilde{l}_L^\pm \nu_l \quad , \quad \tilde{\chi}_2^0 \rightarrow \tilde{l}_L^\pm l^\mp \quad (5.7)$$

is possible.

5. If $m(\tilde{\chi}_1^\pm) \geq m(\tilde{\chi}_1^0) + m(W^\pm)$, $m(\tilde{\chi}_2^0) \geq m(\tilde{\chi}_1^0) + m(Z^0)$ or $m(\tilde{\chi}_2^0) \geq m(\tilde{\chi}_1^0) + m(h_0)$, the decay channels

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^\pm \quad , \quad \tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^0, \quad \tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 h_0 \quad (5.8)$$

are allowed. Figure 2.2 shows, that the chargino can decay into a W^\pm boson and the lightest neutralino via the Wino-Wino-W vertex and the Higgsino-Higgsino-W vertex, while the neutralino can decay into the Z^0 boson and the lightest neutralino only via the Higgsino-Higgsino-Z vertex. As $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$ have a strong Wino component the decay of the $\tilde{\chi}_2^0$ into a Z^0 is suppressed, while the decay of the $\tilde{\chi}_1^\pm$ into a W^\pm may be significant based on the chosen set of parameters.

All other decays are negligible in the considered parameter space. In Figs. 5.7 and 5.8 the branching ratios for the different decay channels can be seen.

Figure 5.7: Branching ratios for the decay of chargino and neutralino as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$. Benchmark point BP1 is at $m_{1/2} = 190 \text{ GeV}/c^2$.

Figure 5.8: Branching ratios for the decay of chargino and neutralino as a function of $m_{1/2}$ at benchmark point BP3 with $\mu < 0$. Benchmark point BP3 is at $m_{1/2} = 190 \text{ GeV}/c^2$.

Figure 5.9: Branching ratio into three leptons split into final states with 0, 1, 2 or 3 τ leptons as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $m_{1/2} = 190 \text{ GeV}/c^2$ for $\mu > 0$ and $\mu < 0$ respectively.

Figure 5.10: Cross section for the production of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ in $p\bar{p}$ collisions at the Tevatron as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $m_{1/2} = 190 \text{ GeV}/c^2$ for $\mu > 0$ and $\mu < 0$ respectively.

5.1.3 The Ratio of the Vacuum Expectation Values of the two Higgs Doublets $\tan \beta$

The value of $\tan \beta$ has an influence on the mixing of the third generation sleptons. With increasing $\tan \beta$ the mixing of the $\tilde{\tau}$ sleptons increases and thus also the difference in mass between the selectron or smuon and the stau slepton. The masses of all other particles show less dependence on $\tan \beta$.

In Figs. 5.12 and 5.13 the branching ratios for the relevant decay channels are shown. For $\tan \beta < 1.5$ perturbation theory breaks down as one of the Yukawa couplings is greater than 10. For $\mu > 0$ and $\tan \beta = 15.3$ ISAJET can not find a solution for the renormalization group equation.

It can be seen that with increasing $\tan \beta$ the decay into third generation sleptons is favored and for this reason more τ leptons will be in the final state. This is especially visible for the decay of the neutralino which does not favor the third generation sleptons as much as the decay of the chargino does. The reason for this is, that the $\tilde{\tau}_1$ slepton is a mixture of $\tilde{\tau}_L$ and $\tilde{\tau}_R$. For increasing $\tan \beta$ the $\tilde{\tau}_1$ becomes more $\tilde{\tau}_L$ -like. As the lighter chargino and the next-to-lightest neutralino are mostly Winos, which couple to left-handed sleptons only, the decay into $\tilde{\tau}_1$ becomes more favored. Figure 5.14 shows that the branching ratio into final states with two electrons or muons and one τ lepton decreases for increasing $\tan \beta$ as the branching ratio of the decay $\tilde{\chi}_2^0 \rightarrow \tilde{\tau}_1^\pm \tau^\mp \rightarrow \tilde{\chi}_1^0 \tau^+ \tau^-$ increases. The dependence of the cross section on $\tan \beta$ follows the mass dependence of $\tilde{\chi}_1^\pm$ and $\tilde{\chi}_2^0$.

Figure 5.11: Mass of the relevant supersymmetric particles as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $\tan \beta = 3$ for $\mu > 0$ and $\mu < 0$ respectively.

Figure 5.12: Branching ratios for the decay of chargino and neutralino as a function of $\tan \beta$ at benchmark point BP1 with $\mu > 0$. Benchmark point BP1 is at $\tan \beta = 3$.

Figure 5.14: Branching ratio into three leptons split into final states with 0, 1, 2 or 3 τ leptons as a function of $\tan \beta$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $\tan \beta$ for $\mu > 0$ and $\mu < 0$ respectively.

Figure 5.15: Cross section for the production of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ in $p\bar{p}$ collisions at the Tevatron as a function of $\tan\beta$ at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $\tan\beta = 3$ for $\mu > 0$ and $\mu < 0$ respectively.

5.1.4 The Common Trilinear Coupling A_0

The neutralino and chargino masses show a low dependence on A_0 , while there is only a very low mass dependence visible for all other supersymmetric particles. Fig. 5.18 for $\mu < 0$ shows that this mass dependence has no major effects on the branching ratios of the different decay channels provided no other decay channels open up. In Fig. 5.17 for $\mu > 0$ the decay channel into on-shell sleptons is open for small trilinear coupling and closed for bigger trilinear couplings. This has an effect on the branching ratios. In general the dependence of the branching ratios on A_0 is rather weak.

Figure 5.16: Mass of the relevant supersymmetric particles as a function of A_0 at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $A_0 = 0$ GeV for $\mu > 0$ and $\mu < 0$ respectively.

Figure 5.17: Branching ratios for the decay of chargino and neutralino as a function of A_0 at benchmark point BP1 with $\mu > 0$. Benchmark point BP1 is at $A_0 = 0$ GeV.

Figure 5.18: Branching ratios for the decay of chargino and neutralino as a function of A_0 at benchmark point BP3 with $\mu < 0$. Benchmark point BP3 is at $A_0 = 0$ GeV.

Figure 5.19: Branching ratio into three leptons split into final states with 0, 1, 2 or 3 τ leptons as a function of A_0 at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $A_0 = 0$ GeV for $\mu > 0$ and $\mu < 0$ respectively.

Figure 5.20: Cross section for the production of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ in $p\bar{p}$ collisions at the Tevatron as a function of A_0 at benchmark point BP1 with $\mu > 0$ (left) and at benchmark point BP3 with $\mu < 0$ (right). The benchmark points BP1 and BP3 are at $A_0 = 0$ GeV for $\mu > 0$ and $\mu < 0$ respectively.

5.2 Description of the Sensitivity of the Analysis

In the following we limit the discussion to the mSUGRA parameters m_0 and $m_{1/2}$ which we have identified as the parameters that have the biggest influence on the sensitivity of the analysis. The following parameters are fixed:

- $\tan \beta = 3$
- $A_0 = 0 \text{ GeV}$
- $\mu > 0$

5.2.1 Regions in mSUGRA Parameter Space

It was shown in section 5.1, that, based on the allowed decay channels, the mSUGRA parameter space can be divided into different phenomenology classes. Figure 5.21 divides the $(m_0, m_{1/2})$ -parameter space into 3 regions:

Figure 5.21: Based on the different dependences of slepton, chargino and neutralino masses on the mSUGRA parameters, regions with different possible decay channels can be defined in the mSUGRA parameter space.

Region A: Only three-body decays via off-shell particles

Region A is defined by the mass relations

$$m(\tilde{\chi}_2^0) < m(\tilde{l}_R^\pm) < m(\tilde{\nu}) < m(\tilde{l}_L^\pm) \quad (5.9)$$

$$m(\tilde{\chi}_1^\pm) < m(\tilde{l}_R^\pm) < m(\tilde{\nu}) < m(\tilde{l}_L^\pm) \quad (5.10)$$

$$m(\tilde{\chi}_2^0) < \begin{cases} m(\tilde{\chi}_1^0) + m(Z^0) \\ m(\tilde{\chi}_1^0) + m(h^0) \end{cases} ; m(\tilde{\chi}_1^\pm) < m(\tilde{\chi}_1^0) + m(W^\pm) \quad (5.11)$$

where $\tilde{l}_R^\pm = \tilde{e}_R^\pm, \tilde{\mu}_R^\pm, \tilde{\tau}_1^\pm$ and $\tilde{l}_L^\pm = \tilde{e}_L^\pm, \tilde{\mu}_L^\pm, \tilde{\tau}_2^\pm$. As in mSUGRA $m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0)$ the relations 5.9 and 5.10 are equivalent⁵. In the parameter space considered relation 5.11 holds for $m_{1/2} < 250 \text{ GeV}/c^2$.

In region A only three-body decays via off-shell particles are possible and the relevant decays are

- via off-shell $W^{\pm*}$ or Z^{0*} boson

$$\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \tilde{\chi}_1^0 \begin{cases} l^+ l^- \\ q \bar{q} \\ \nu \bar{\nu} \end{cases} ; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \tilde{\chi}_1^0 \begin{cases} l^\pm \nu_l \\ q_1 \bar{q}_2 \end{cases} \quad (5.12)$$

- via off-shell right-handed slepton $\tilde{e}_R, \tilde{\mu}_R$ or $\tilde{\tau}_1$

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^{\pm*} l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^- ; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^{\pm*} \nu_l \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (5.13)$$

- via off-shell sneutrino $\tilde{\nu}_e, \tilde{\nu}_\mu$ or $\tilde{\nu}_\tau$

$$\tilde{\chi}_2^0 \rightarrow \tilde{\nu}_l^* \bar{\nu}_l \rightarrow \tilde{\chi}_1^0 \nu_l \bar{\nu}_l ; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{\nu}_l^* l^\pm \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (5.14)$$

The decay via off-shell $W^{\pm*}$ or Z^{0*} boson is dominant for higher m_0 . At the border of region A it is $m(\tilde{\chi}_2^0) \approx m(\tilde{l}_R^\pm)$ and the decay via off-shell slepton is dominant.

⁵See section 2.2.5 for details.

Region B: Decay via on-shell right-handed sleptons dominant

Region B is defined by the mass relations

$$m(\tilde{l}_R^\pm) < m(\tilde{\chi}_2^0) < m(\tilde{\nu}) < m(\tilde{l}_L^\pm) \quad (5.15)$$

$$m(\tilde{l}_R^\pm) < m(\tilde{\chi}_1^\pm) < m(\tilde{\nu}) < m(\tilde{l}_L^\pm) \quad (5.16)$$

$$m(\tilde{\chi}_2^0) < \begin{cases} m(\tilde{\chi}_1^0) + m(Z^0) \\ m(\tilde{\chi}_1^0) + m(h^0) \end{cases} ; m(\tilde{\chi}_1^\pm) < m(\tilde{\chi}_1^0) + m(W^\pm) \quad (5.17)$$

where $\tilde{l}_R^\pm = \tilde{e}_R^\pm, \tilde{\mu}_R^\pm, \tilde{\tau}_1^\pm$ and $\tilde{l}_L^\pm = \tilde{e}_L^\pm, \tilde{\mu}_L^\pm, \tilde{\tau}_2^\pm$. In region B there are three-body decays via off-shell particles and two-body decays via on-shell right-handed sleptons possible. The relevant decays are

- via on-shell right-handed slepton $\tilde{e}_R, \tilde{\mu}_R$ or $\tilde{\tau}_1$

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^-; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^\pm \nu_l \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (5.18)$$

- via off-shell $W^{\pm*}$ or Z^{0*} boson

$$\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \tilde{\chi}_1^0 \begin{cases} l^+ l^- \\ q \bar{q} \\ \nu \bar{\nu} \end{cases} ; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \tilde{\chi}_1^0 \begin{cases} l^\pm \nu_l \\ q_1 \bar{q}_2 \end{cases} \quad (5.19)$$

- via off-shell sneutrino $\tilde{\nu}_e, \tilde{\nu}_\mu$ or $\tilde{\nu}_\tau$

$$\tilde{\chi}_2^0 \rightarrow \tilde{\nu}_l^* \bar{\nu}_l \rightarrow \tilde{\chi}_1^0 \nu_l \bar{\nu}_l; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{\nu}_l^* l^\pm \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (5.20)$$

As a decay via on-shell particle becomes available the decay channel becomes dominant. In region B this is the decay via right-handed on-shell sleptons as soon as there is enough phase space for the decay products. If there is not enough phase space for the products of the decay via an on-shell slepton, which is the case at the border of region A to B, the decays via off-shell particles, mostly sleptons, have a significant branching ratio.

It is shown in appendix B, that the combination of PYTHIA and ISAJET does not handle mass widths correctly. As a result in a band of approximately 4 GeV around the transition area from three-body decay via off-shell particles to sequential two-body decay via on-shell particles the branching ratios for the used decay channels are artificial and do not represent the predictions by mSUGRA.

Region C: Decay via on-shell right-handed sleptons and sneutrinos dominant

Region C is defined by the mass relations

$$m(\tilde{l}_R^\pm) < m(\tilde{\nu}) < m(\tilde{\chi}_2^0) < m(\tilde{l}_L^\pm) \quad (5.21)$$

$$m(\tilde{l}_R^\pm) < m(\tilde{\nu}) < m(\tilde{\chi}_1^\pm) < m(\tilde{l}_L^\pm) \quad (5.22)$$

$$m(\tilde{\chi}_2^0) < \begin{cases} m(\tilde{\chi}_1^0) + m(Z^0) \\ m(\tilde{\chi}_1^0) + m(h^0) \end{cases} ; m(\tilde{\chi}_1^\pm) < m(\tilde{\chi}_1^0) + m(W^\pm) \quad (5.23)$$

where $\tilde{l}_R^\pm = \tilde{e}_R^\pm, \tilde{\mu}_R^\pm, \tilde{\tau}_1^\pm$ and $\tilde{l}_L^\pm = \tilde{e}_L^\pm, \tilde{\mu}_L^\pm, \tilde{\tau}_2^\pm$. In region C there are off-shell three-body decays and decays via on-shell right-handed sleptons possible. The relevant decays are

- via on-shell sneutrino $\tilde{\nu}_e, \tilde{\nu}_\mu$ or $\tilde{\nu}_\tau$

$$\tilde{\chi}_2^0 \rightarrow \tilde{\nu}_l \bar{\nu}_l \rightarrow \tilde{\chi}_1^0 \nu_l \bar{\nu}_l; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{\nu}_l l^\pm \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (5.24)$$

- via on-shell right-handed slepton $\tilde{e}_R, \tilde{\mu}_R$ or $\tilde{\tau}_1$

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^-; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^\pm \nu_l \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (5.25)$$

- via off-shell $W^{\pm*}$ or Z^{0*} boson

$$\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \tilde{\chi}_1^0 \begin{cases} l^+ l^- \\ q \bar{q} \\ \nu \bar{\nu} \end{cases} ; \quad \tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \tilde{\chi}_1^0 \begin{cases} l^\pm \nu_l \\ q_1 \bar{q}_2 \end{cases} \quad (5.26)$$

In region C on-shell decays via right-handed sleptons and sneutrinos are available. Which of the two on-shell decay channels is dominant depends on the mixing of the chargino and neutralino.

It has to be noted that the division into regions is only valid up to a couple of GeV. For example at the transition from region A to B the border is at $m(\tilde{\chi}_2^0) = m(\tilde{\tau}_1)$ even though for the third generation decay the decay changes from off-shell slepton, $W^{\pm*}$ or Z^{0*} boson to on-shell slepton is at $m(\tilde{\chi}_2^0) = m(\tilde{\tau}_1^\pm) + m(\tau^\mp)$. At the transition from region A to B the region border is similar for all three generations; at the transition from region B to C a difference between first or second and third generation slepton to sneutrino transition is visible.

5.2.2 Cross Section for Associated Chargino-Neutralino Production

We calculate the cross section for associated chargino-neutralino production in $\sqrt{s} = 1.96$ TeV $p\bar{p}$ collisions at the Tevatron with PROSPINO 2.0[35]⁶. It was shown in section 5.1, that the main dependence of the cross section for associated chargino-neutralino production is on $m_{1/2}$. Figure 5.22 shows the cross section in the $(m_0, m_{1/2})$ -plane.

Figure 5.22: Cross section for the production of an associated chargino-neutralino pair in $\sqrt{s} = 1.96$ TeV $p\bar{p}$ collisions at the Tevatron as a function of m_0 and $m_{1/2}$.

5.2.3 Branching Ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into Three Leptons

Together with the masses, which affect the cross section limit, the branching ratio of the produced chargino-neutralino pair into three leptons and the cross section for its production are the most important quantities for an exclusion of parts of the mSUGRA parameter space. As the cross section for the production has a rather simple dependence on the mSUGRA parameters m_0 and $m_{1/2}$ the branching ratio into three leptons is the major factor that is determining the sensitivity of the discussed trilepton analysis.

The branching ratio can be seen in Fig. 5.23. Starting in region A for high m_0 the decay is dominated by the exchange of an off-shell $W^{\pm*}$ or Z^{0*} boson. As this decay can lead

⁶The particle spectrum used was produced with ISAJET 7.75[33].

Figure 5.23: Branching ratio for the decay of a chargino-neutralino pair into three leptons, where leptons are electrons, muons and τ leptons.

to final states with quarks, neutrinos and leptons the branching ratio into three leptons is comparably low and a lot of events have quarks in the final state⁷. Decays into quarks are not detectable with a trilepton signature. Close to the line where $m(\tilde{\chi}_2^0) \approx m(\tilde{\chi}_1^\pm) \approx m(\tilde{l}_R^\pm)$ the decay via off-shell slepton becomes more important. As this decay goes into leptons with 100% branching ratio, the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons increases. At the border of region A to B the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons drops for a width at the order of 1 GeV. This is an artefact of the combination of ISAJET and PYTHIA. For a more detailed description of the effect see appendix B. In region B the decay via on-shell right-handed sleptons is dominant. As this decay has 100% leptons in the final state, the branching ratio into three leptons increases. In region C the decay via on-shell sneutrinos becomes available and the branching ratio decreases again. From the point of the branching ratio the exclusion limit should be optimal in region B.

⁷For details see also Fig. 5.2.

5.2.4 Average Number of τ Leptons per Event

Even though the branching ratio into three leptons favors region B for exclusion, the average number of τ leptons disfavors region B. It can be seen in section 4.6.3 that the purity of the channels with three leptons is significantly better than the purity of the channels with two leptons and one track. The average number of τ leptons is a measure for the ratio of the number of events in the two channel categories.

In Fig. C it can be seen that the average number of τ leptons per event in region B is significantly higher. The reason is that the chargino is a mixed mass eigenstate which is dominated by the Higgsino gauge eigenstate. The coupling of the Higgsino to the third generation $\tilde{\tau}_1$ slepton is significantly higher than the coupling to the selectron \tilde{e}_R and smuon $\tilde{\mu}_R$. As a decay via $\tilde{\tau}_1$ slepton yields τ leptons the average number of τ leptons increases.

Figure 5.24: The mean number of τ leptons per event is a measure for the number of events in the trilepton versus the number of events in the dilepton + track channel. The drop in the mean number of τ leptons at the border of region A to B is due to the artefact of the setup of PYTHIA and ISAJET discussed in appendix B.

5.3 Limits on the Production Cross Section and the Chargino Mass

Within errors the results of the search for trileptons in section 4.6.3 have been consistent with the predictions for the standard model background. As no deviations from the Standard Model have been found, it is possible to obtain an observed upper limit on the cross section multiplied by the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons in mSUGRA. The observed upper limit is the maximal cross section times branching ratio that is consistent at 95% confidence level with the number of observed events.

5.3.1 Calculation of a Limit on the Production Cross Section

Based on the results from section 4.6.3 a 95% confidence level limit on the cross section and branching ratio for the process $\tilde{\chi}_2^0 \tilde{\chi}_1^\pm \rightarrow 3$ leptons, where a lepton can be an electron, a muon or a τ lepton, was calculated. As suggested by the CDF Statistics Committee[57] we use the MCLIMIT software[58] to calculate confidence levels.

This software is using the frequentist definition of a probability and is comparing the signal + background hypothesis H_1 (“Supersymmetry is realized in nature”) to the null-hypothesis H_0 (background only, “Supersymmetry is not realized in nature”). If s_i is the expected signal, b_i the expected background and d_i the observed number of events in channel i according to the Poisson distribution the likelihood ratio for channel i Q_i is defined as

$$Q_i = \frac{P(H_1 | \text{data})}{P(H_0 | \text{data})} = \frac{\exp - (s_i + b_i) (s_i + b_i)^{d_i}}{d_i!} \bigg/ \frac{\exp - (b_i) (b_i)^{d_i}}{d_i!} \quad (5.27)$$

and the combined likelihood ratio as

$$Q = \prod_i Q_i. \quad (5.28)$$

The confidence level for excluding the signal + background hypothesis is

$$CL_{s+b} = P_{s+b} (Q < Q_{\text{obs}}) \quad (5.29)$$

and similarly CL_b for excluding the null-hypothesis. For this analysis the modified frequency confidence levels

$$CL_s = \frac{CL_{s+b}}{CL_b} \quad (5.30)$$

are used. In the following the cross section multiplied by branching ratio into three leptons $\tilde{\chi}_1^\pm \tilde{\chi}_2^0 \rightarrow 3 \text{ leptons}$ for which $CL_s(\sigma(\tilde{\chi}_1^\pm \tilde{\chi}_2^0) \times \text{BR}(\tilde{\chi}_1^\pm \tilde{\chi}_2^0 \rightarrow 3 \text{ leptons})) = 0.05$, the 95% confidence level, is determined.

5.3.2 Limit on the Production Cross Section

In order to set a limit on the cross section for the production of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ 87 Monte Carlo points were produced. The supersymmetric particle spectrum from ISAJET 7.51[33] is used to generate events in PYTHIA 6.216[31]. τ decays are treated by TAUOLA[34]; full detector and trigger simulation is done with the CDF software MCPRODUCTION 6.1.4mc. For all Monte Carlo points we use mSUGRA with $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$ and varied m_0 and $m_{1/2}$. The values of m_0 and $m_{1/2}$ for the produced Monte Carlo samples can be obtained from Fig. 5.25. As stated in section 5.3.1 the MCLIMIT software[58] was used to calculate a 95% confidence level upper limit for the cross section multiplied with the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons.

Figure 5.25: Monte Carlo points used for obtaining a limit on the $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ production cross section. For the red points supersymmetry does not manifest itself at this set of parameters; for the green points exclusion is not possible.

The observed upper limit on the cross section for chargino-neutralino production multiplied by the branching ratio of their decay into three leptons (lepton= e, μ, τ) set by this

analysis can be found in Fig. 5.26. The observed limit on the cross section decouples the effects of the branching ratio and the production cross section from kinematic effects⁸ on the limit set by this analysis. Through the kinematic properties of the event the observed limit is indirectly dependent on mSUGRA. For a more detailed explanation of the features of Fig. 5.26 see section 5.3.3.

Figure 5.26: Observed limit on the production cross section multiplied with the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons, where leptons are electrons, muons and τ leptons.

⁸The observed upper limit on $\sigma \times \text{BR}$ is still including effects from the number of events in the trilepton and the dilepton + track channels and thus the mean number of τ leptons in the final state.

5.3.3 Limit on the Chargino Mass

Figure 5.27: Limit on the mass of the chargino at $m_0 = 60 \text{ GeV}/c^2$ in region B, where two-body decays are dominant.

As the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons and the cross section for the production of chargino and neutralino are determined by the mSUGRA parameters, an exclusion in mSUGRA can be calculated. The theory cross section was calculated with PROSPINO 2.0[35]; the theoretical branching ratio of chargino and neutralino into three leptons was calculated with PYTHIA 6.409[31]. Both programs use the particle spectrum of ISAJET 7.75[33] as an input.

In Fig. 5.27 the theory cross section times branching ratio from mSUGRA and the observed upper limit is plotted as a function of $m_{1/2}$ at benchmark point BP1 in region B, where the decay is dominantly via on-shell right-handed sleptons. This analysis is able to exclude that supersymmetry manifests itself at all parameter points where the upper limit is lower than the theoretical quantity. In Fig. 5.27 it is possible to exclude chargino masses below approximately 145 GeV for $m_0 = 60 \text{ GeV}$, $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$. The collider LEP has set a limit on the chargino mass based on its center-of-mass energy at $m(\tilde{\chi}_1^\pm) = 103.5 \text{ GeV}/c^2$ [59]; the limit is shown.

Figure 5.28: Limit on the mass of the chargino at $m_0 = 100 \text{ GeV}/c^2$ in region A, where three-body decays are dominant.

In Fig. 5.28 the corresponding plot can be seen as a function of $m_{1/2}$ at $m_0 = 100 \text{ GeV}/c^2$, $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$ and $\mu > 0$. Up to approximately $127 \text{ GeV}/c^2$ this is in region A, where the decay is dominantly via off-shell particles $W^{\pm*}$, Z^{0*} , $\tilde{l}_R^{\pm*}$. Here the observed limit and the theoretical expectation follow the shape from Fig. 5.27, but are at lower $\sigma \times \text{BR}$. The cross section at same values of $m_{1/2}$ should be comparable, but the branching ratio into three leptons is significantly lower in this regions which leads to a lower theory expectation. At $m_{\tilde{\chi}_1^\pm} > 127 \text{ GeV}/c^2$ the observed upper limit increases. The decay here is mostly via an on-shell slepton and as the slepton mass is approximately the mass of the neutralino there is very small phase space for the lepton produced in the decay

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp. \quad (5.31)$$

The probability for the lepton not to pass the minimum requirements on the lepton transverse momentum⁹ increases and so does the observed upper limit. Once the phase space

⁹For the p_T requirements of the analysis see section 4.3.

for the produced lepton is big enough, more leptons pass the minimum transverse momentum requirements and the observed limit is decreases again. The limit on the chargino mass here is approximately $127 \text{ GeV}/c^2$.

It has to be noted that these limits are only valid for four fixed parameters: m_0 , $\tan\beta$, A_0 and μ . It was shown in section 5.1 that the parameters most important for the masses of the important supersymmetric particles are m_0 and $m_{1/2}$. In what follows we relax the requirement that m_0 is fixed and examine the sensitivity of the analysis for varying m_0 and $m_{1/2}$, but fixed $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$ and $\mu > 0$. Figure 5.25 documents the Monte Carlo points that we have produced. It can be seen that the Monte Carlo points are not in a regular grid; in section 5.2.1 several regions with different phenomenology have been introduced and we followed the shape of these regions.

For every Monte Carlo point the observed upper limit on $\sigma \times \text{BR}$ was determined. The quantity

$$X = \frac{\sigma \times \text{BR}(\text{Observed limit}) - \sigma \times \text{BR}(\text{Theory})}{\sigma \times \text{BR}(\text{Theory})} \quad (5.32)$$

is interpolated by Delauney triangulation with ROOT and is plotted in Fig. 5.29. The region where $X < 0$ can be excluded and is displayed in Fig. 5.30. It can be seen that the

Figure 5.29: Interpolation of the observed upper limit and the theory cross section and branching ratio into three leptons to obtain an exclusion region in mSUGRA

exclusion region is split into two parts with a strip of approximately 10 to 15 GeV, where no exclusion can be claimed. Following the explanation for Fig. 5.28 a soft lepton that can not

always pass the p_T cuts is produced and the sensitivity of the analysis worsens. The exact value of the observed upper limit for the cross section is highly dependent on a fine change in the parameters m_0 and $m_{1/2}$, so that the interpolation is not reliable and an exclusion can not be claimed in this regions.

Figure 5.30: 95% confidence level exclusion region in mSUGRA

Nevertheless a search for two leptons with equal charge should have sensitivity in this strip. In 50% of all events the soft lepton has a different charge than the other two leptons. As one soft leptons implies two harder leptons a search for like-sign leptons that is specifically designed to look for supersymmetry in this strip can search for two hard leptons with same charge. The standard model background should be low and preliminary studies have shown such an analysis has sensitivity in the biggest part of this strip.

Figure 5.31 shows an overlay of the theoretical production cross section multiplied by the branching ratio of $\tilde{\chi}_1^{\pm} \tilde{\chi}_2^0$ into three leptons and the exclusion region in mSUGRA. It can be seen that except at the border of region A and B the exclusion region follows the contour of $\sigma \times \text{BR}$. This can be taken as a proof that the important quantities for the exclusion

are the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons and the production cross section. The kinematics of the event have an impact on the rather smooth observed upper limit at the border of regions where small mass differences exist only.

Figure 5.31: Overlay of the theoretical production cross section multiplied by the branching ratio of $\tilde{\chi}_1^\pm \tilde{\chi}_2^0$ into three leptons and the exclusion region in mSUGRA

5.4 Comparison of the Results to Previous Searches

Searches for supersymmetry have been carried out at several high energy collider experiments. At the Tevatron both CDF and DØ have been looking for chargino and neutralino production; however, most of the current limits on supersymmetric models are derived by analyses using data of the collider LEP.

5.4.1 Results of LEP2

The Joint SUSY Working Group by the experiments ALEPH, DELPHI, L3 and OPAL has published a combination of the searches for supersymmetry and other limiting searches of the individual experiments[59]. The searches most relevant for this analysis are

- Combined LEP Chargino Results for low DM,
- Combined LEP Chargino Results for large m_0 ,

- Combined LEP Selectron/Smuon/Stau Results,
- Interpretation of the results in Minimal SUGRA.

All four LEP experiments have searched for charginos in the decay channel into leptons, leptons+jets and jets. In the combined LEP Chargino Results for large m_0 the limits are combined under the assumption that the chargino decays via a $W^{\pm*}$ boson. It can be seen in section 5.1.1 that this is the case for $m_0 \gg 100 \text{ GeV}/c^2$ in the parameter space considered in this thesis, but for lower m_0 the decay via on- or off-shell sleptons may be dominant. Overall for $m(\tilde{\nu}_l) > 300 \text{ GeV}/c^2$ the exclusion limit from 206-208 GeV data is

$$m(\tilde{\chi}_1^{\pm}) > 103.5 \text{ GeV}/c^2. \quad (5.33)$$

The condition $m(\tilde{\nu}_l) > 300 \text{ GeV}/c^2$ is fulfilled for high m_0 , but might not be fulfilled for small m_0 .

The search for chargino with low DM, where $DM = m(\tilde{\chi}_1^{\pm}) - m(\text{LSP})$, is done in the MSSM framework. The published limits for $0 \text{ GeV}/c^2 < DM < 10 \text{ GeV}/c^2$ and high m_0 or $\mu \ll M_2$ are

$$m(\tilde{\chi}_1^{\pm}) > 92.4 \text{ GeV}/c^2 \text{ (for } \mu \ll M_2\text{);} \quad m(\tilde{\chi}_1^{\pm}) > 91.9 \text{ GeV}/c^2 \text{ (for high } m_0\text{).} \quad (5.34)$$

The LEP search for right-handed sleptons has also published limits. The exclusion regions for the interpretation of the LEP results in mSUGRA can be found in Fig. 5.32.

5.4.2 CDF Results

CDF has published previous results with approximately 1 fb^{-1} of data in the like-sign channels $e^{\pm}e^{\pm}$, $e^{\pm}\mu^{\pm}$ and $\mu^{\pm}\mu^{\pm}$ [60], the non-exclusive high p_T channels eel , $e\mu l$, $\mu\mu l$ and μel [61], the low p_T channel $\mu\mu l$ [62] and a trilepton channel including a track eeT [63]. A combination of the channels can be found in [64].

A limit in the mSUGRA model for $m_0 = 60 \text{ GeV}$, $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$ and varying $m_{1/2}$ is shown in Fig. 5.33. It was not possible to derive a limit on the chargino mass. CDF also presents limits in a scenario without slepton mixing and same couplings for all slepton generations. mSUGRA with the same set of parameters as above is used

Figure 5.32: Excluded regions by the LEP experiments in the $(m_0, m_{1/2})$ -plane of mSUGRA for fixed $\tan \beta$, A_0 , $\text{sgn}(\mu)$.

and slepton mixing in the mixing matrix used by SOFTSUSY is turned off. This procedure decreases the number of τ leptons in the final state and leads to a higher acceptance of the analysis. A limit of $m(\tilde{\chi}_1^\pm) > 129 \text{ GeV}$ can be derived for this special set of parameters. In a model with $\tan\beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$ and

$$m(\tilde{\chi}_1^\pm) = m(\tilde{\chi}_2^0) = m(\tilde{\chi}_1^0) \quad (5.35)$$

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l) = \text{BR}(W^\pm \rightarrow l^\pm \nu_l) \quad (5.36)$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 l^+ l^-) = \text{BR}(Z \rightarrow l^+ l^-) \quad (5.37)$$

the limit on $\sigma \times \text{BR}$ is shown in [64], but it was not possible to derive a limit on the chargino mass.

Figure 5.33: Excluded chargino masses for CDF and DØ. CDF was using plain mSUGRA, whereas DØ was working in a mSUGRA inspired MSSM scenario with no slepton mixing.

5.4.3 DØ Results

A similar search for chargino and neutralino production in a trilepton final state was done by DØ[65, 66] with up to 1.7 fb^{-1} of data. DØ is presenting results in a mSUGRA inspired MSSM scenario, where slepton mixing is turned off; it is assumed that all three slepton generation have the same couplings and

$$m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0) \approx 2 \times m(\tilde{\chi}_1^0). \quad (5.38)$$

For the 3l-max scenario the chargino and slepton mass parameters are chosen in a way that $m(\tilde{l}) > m(\tilde{\chi}_2^0)$ and the branching ratio $\text{BR}(\tilde{\chi}_2^0 \tilde{\chi}_1^\pm \rightarrow 3 \text{ leptons})$ is maximized. In

practice the maximization of the branching ratio is achieved by setting $m(\tilde{l}_R^\pm) \gtrsim m(\tilde{\chi}_2^0)$. This requirement ensures that the decay is dominantly via off-shell sleptons. Similar to the no slepton mixing scenario used by CDF these requirements lead to less τ leptons in the final state and thus a higher acceptance. The heavy squarks scenario squarks are set to high masses to increase the production cross section of chargino-neutralino pairs¹⁰. Additionally a scenario with high m_0 , where the chargino and neutralino decay is dominantly via an off-shell $W^{\pm*}$ or Z^{0*} boson, is shown. As the branching ratio into leptons is significantly smaller in this scenario no limit on the chargino mass can be derived. The derived limits for the 3l-max and the heavy slepton scenario can be seen in Fig. 5.33.

It should be noted that the previous CDF and DØ results are only applicable for a very restrained set of supersymmetric models and choice of parameters. It is tried to generalize the results obtained in this thesis to a broader range of supersymmetric models and sets of parameters in chapter 6.

¹⁰See section 4.1 for details.

Chapter 6

Model-Independent Interpretation of the Results

6.1 Description of the Method

Section 5.4 shows that the results of CDF and DØ have always been interpreted in a specific model. Furthermore the models have major differences, ranging from plain mSUGRA to the MSSM scenario of DØ, where several other assumptions are used to maximize the sensitivity. The development of a model-independent description of the analysis results is investigated in this section.

Limits on the cross section as calculated in section 5.3 are dependent on

1. the expected Standard Model and non-physics background and the observed number of events in data and
2. the acceptance of the analysis for the supersymmetric signal.

Whereas the expected background and the observed number of events in data are completely model-independent and depend only on the analysis, the acceptance of the analysis for the supersymmetric signal is naturally dependent on the model for which limits are to be derived.

The acceptance itself is dependent on the type and the kinematics of the reconstructed analysis objects. For the acceptance the difference between a reconstructed electron and a reconstructed muon is negligible, but electrons or muons and isolated tracks have different purities. Since for signal tracks mainly originate from decays of τ leptons, the ratio of the

number of events with i τ leptons ($i = 0, 1, 2, 3$) and the number of all events with 3 leptons plays an important role. We define this ratio as

$$F_i = \frac{\text{BR}(\tilde{\chi}_1^\pm \tilde{\chi}_2^0 \rightarrow i\tau + (3-i)l_{e/\mu} + X)}{\text{BR}(\tilde{\chi}_1^\pm \tilde{\chi}_2^0 \rightarrow 3l + X)} = \quad (6.1)$$

$$= \frac{\text{Number of tripleton events with } i \text{ } \tau \text{ leptons}}{\text{Number of total tripleton events}}, \quad (6.2)$$

where $l = e, \mu, \tau$ and $l_{e/\mu} = e, \mu$. If it is possible to obtain the acceptance A_i of a signal sample that is only consisting of events with i τ leptons in the final state, the overall acceptance is

$$A = \sum_{i=0}^3 F_i A_i. \quad (6.3)$$

It was shown earlier in this thesis that the acceptance of the analysis is dependent on the mass spectrum of the involved particles. In this section we will restrict us to the cases

1. $m(\tilde{\chi}_1^0) < m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0) < \text{mass of all other supersymmetric particles}$
2. $m(\tilde{\chi}_1^0) < m(\tilde{l}_R^\pm) < m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0) < \text{mass of all other supersymmetric particles,}$
where \tilde{l}_R stands for the lighter selectron, smuon and stau.

These assumptions include that $m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0)$, which is the case in several supersymmetric models. Case 2 here additionally includes the assumption that the sleptons are mass degenerate. This assumption is different from the assumption of $D\tilde{O}$ as we explicitly treat the couplings of the stau differently than the coupling of the selectron or smuon. Considering Eqn. 2.20 this is a major improvement over the model used by $D\tilde{O}$. At benchmark point BP1 the difference in mass between stau and selectron or smuon is 0.1 GeV^1 . If the mass difference of the electron or muon and τ lepton is also considered, for a neutralino the decay via a $\tilde{\tau}$ slepton would even be disfavored over the decay via \tilde{e} or $\tilde{\mu}$. This could hardly explain the differences in branching ratio seen in Fig. 5.2. The difference of the branching ratio of the decay via a stau slepton and the decay via selectron or smuon is predominantly due to the fact of the different couplings and not the difference in mass. The effects of the coupling can fully be accounted for by the branching ratios F_i , $i = 0, 1, 2, 3$.

Using these assumptions the relevant part of the mass spectrum is fully described by

¹See Table 5.2 for details.

1. the chargino mass $m(\tilde{\chi}_1^\pm)$ and thus implicitly the mass of the neutralino,
2. the LSP mass $m(\tilde{\chi}_1^0)$,
3. the mass of the lighter sleptons $m(\tilde{l}_R^\pm)$.

An equivalent parameterization that is closer to the experimentally relevant quantities uses the parameters

1. chargino mass $m(\tilde{\chi}_1^\pm)$ and thus implicitly the mass of the neutralino,
2. $\Delta M_1 = m(\tilde{\chi}_1^\pm) - m(\tilde{l}_R^\pm)$,
3. $\Delta M_2 = m(\tilde{\chi}_1^\pm) - m(\tilde{\chi}_1^0)$.

As we don't consider the case where a slepton is the LSP², it is $\Delta M_1 < \Delta M_2$.

If it is possible to measure the acceptance of the final states split up according to their τ content A_i as a function of $m(\tilde{\chi}_1^\pm)$, ΔM_1 , ΔM_2 , general limits dependent on

- the masses $m(\tilde{\chi}_1^\pm)$, ΔM_1 , ΔM_2
- the branching ratios F_i , $i = 0, 1, 2, 3$

can easily be derived for other models by using Eqn. 6.3.

6.2 Determination of the Acceptance Functions

In mSUGRA, $m(\tilde{\chi}_1^0) \approx m(\tilde{\chi}_2^0)$ ³. For technical reasons we have reduced the set of mass parameters in section 6.1 to $m(\tilde{\chi}_1^\pm)$ and $\Delta M_1 = m(\tilde{\chi}_1^\pm) - m(\tilde{l}_R^\pm)$; ΔM_2 is determined by the relations of mSUGRA. A way to produce samples where all three parameters are free, is described in appendix D.

As full CDF detector simulation is very CPU time consuming, we use PYTHIA 6.409[31] and ISASUGRA 7.75[33] to produce Monte Carlo samples. The decay of the τ lepton is done by TAUOLA 2.1[34]. We use mSUGRA and vary m_0 and $m_{1/2}$ in order to get samples with

²A case with a charged particle as the LSP would not explain the WMAP dark matter observations.

³For details see section 2.47.

different mass parameters. $A_0 = 0 \text{ GeV}$, $\tan\beta = 3$ and $\mu > 0$ are kept constant. For every considered realization of supersymmetry⁴ we produce four Monte Carlo subsamples which consist of events where $\tilde{\chi}_2^0 \tilde{\chi}_1^\pm$ are forced to decay into three leptons among which $i = 0, 1, 2, 3$ leptons are τ leptons. No further detector simulation is used. In section 6.3 we show that at the level of precision needed for this model-independent approach standalone PYTHIA without full CDF detector simulation is sufficient.

In the PYTHIA Monte Carlo samples we select events in a way to mimic the trilepton analysis described in section 4. Similar to the analysis channels in Table 4.6 we select events with three leptons or two leptons and one isolated track⁵ (lepton= e, μ) passing the criteria documented in Table 6.1. Missing E_T is calculated by summing the vector components of the transverse momentum of neutrinos and LSP's in the event. The acceptance is defined

Variable	Selection
$p_T^{1,2,3}$	$> 15, 5, 5 \text{ GeV}$
$ \eta^{1,2,3} $	< 1.1
\cancel{E}_T	$> 20 \text{ GeV}$
m_{OS}^1	$> 20 \text{ GeV}, \notin [76 \text{ GeV}, 106 \text{ GeV}]$
m_{OS}^2	$> 13 \text{ GeV}, \notin [76 \text{ GeV}, 106 \text{ GeV}]$

Table 6.1: Selection criteria for the determination of the acceptance in the model-independent approach. m_{OS}^i , $i = 1, 2$ are the two invariant masses of oppositely charged particles that can be obtained from the three analysis objects.

by

$$A_i = \frac{\text{Number of events that are able to pass the cuts}}{\text{Total number of events}} \quad (6.4)$$

and determined individually for the four Monte Carlo samples. We show the acceptance split up into subsamples in Fig. 6.1. It has to be noted that the current trilepton analysis has very small acceptance to events with 2 or more τ leptons as the analysis currently only uses trilepton and dilepton + track channels. Including channels with more than one track would result in a considerable increase of background.

⁴A realization of supersymmetry here is fully defined by the mass parameters.

⁵Similar to the isolation requirement in section 4 we require that the sum of p_T of all other tracks in a cone of 0.4 in the (η, ϕ) -plane around the considered track is less than 10% of the track's p_T .

Figure 6.1: Analysis acceptance split into channels according to the number of τ leptons in the trilepton final state

It can be seen that the acceptance is a smooth function unless the mass differences $\Delta M_1 = m(\tilde{\chi}_1^\pm) - m(\tilde{l}_R^\pm)$ or $m(\tilde{\chi}_1^\pm) - m(\tilde{\nu})$ are small. For small mass differences new decay channels open up. Additionally soft leptons are produced and sophisticated detector simulation becomes important; standalone PYTHIA Monte Carlo is not reliable there. We ensure that $m(\tilde{\nu}) > m(\tilde{\chi}_1^\pm)$ and $\Delta M_1 < -2 \text{ GeV}$ or $\Delta M_1 > 15 \text{ GeV}$ to avoid these regions. In the regions of smooth behavior we fit the acceptance with a function of the type

$$A = p_0 + p_1 \left(\frac{M(\tilde{\chi}_1^\pm)}{100 \text{ GeV}} \right) + p_2 \left(\frac{M(\tilde{\chi}_1^\pm)}{100 \text{ GeV}} \right)^2. \quad (6.5)$$

The results for the individual subsamples can be found in Table 6.2. The fits approximate the measured acceptance within 20%. A comparison of the fit of the acceptance and the acceptance itself for various sets of mSUGRA parameters can be found in Table 6.3.

Subsample	p_0	p_1	p_2
0 τ 's	-0.19	0.49	-0.14
1 τ 's	-0.044	0.14	0
2 τ 's	-0.12	0.19	-0.055
3 τ 's	-0.008	0.01	0

Table 6.2: The values of the parameters of the acceptance fits in the different subsamples. The fit function is given by Eqn. 6.5.

m_0	$m_{1/2}$	A_0	$\tan \beta$	Actual Acc.	Calc. Acc.
60	190	0	3	0.08810	0.08000
60	190	-200	3	0.07840	0.07160
70	190	100	5	0.08040	0.07532
70	180	0	10	0.03210	0.03066
70	180	200	10	0.03880	0.03801
120	180	200	3	0.11590	0.11322
120	180	-200	5	0.12850	0.12183
120	180	200	10	0.10550	0.10923
1000	200	0	10	0.15890	0.15250
1000	200	-200	10	0.16300	0.15421
1000	200	200	10	0.16160	0.15250

Table 6.3: Comparison of the actual acceptance from Pythia (Actual Acc.) and the acceptance calculated using the fits (Calc. Acc.) for several sets of mSUGRA points. It is $\mu > 0$ for all points.

The acceptance from full detector simulation Monte Carlo and standalone PYTHIA Monte Carlo is different. To account for this difference we introduce a scale factor of

$$\frac{A_{\text{CDF}}}{A_{\text{Pythia}}} = 0.169 \quad (6.6)$$

for the region where $m(\tilde{l}_R^\pm) < m(\tilde{\chi}_1^\pm)$ and

$$\frac{A_{\text{CDF}}}{A_{\text{Pythia}}} = 0.222 \quad (6.7)$$

for the region where $m(\tilde{l}_R^\pm) > m(\tilde{\chi}_1^\pm)$. The scale factor for the light slepton region B⁶ in Eqn. 6.6 was measured at the mSUGRA point $m_0 = 60 \text{ GeV}/c^2$, $m_{1/2} = 190 \text{ GeV}/c^2$, $\tan \beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$ and the scale factor at the heavy slepton region A⁶ in Eqn. 6.6 $m_0 = 100 \text{ GeV}/c^2$, $m_{1/2} = 180 \text{ GeV}/c^2$, $\tan \beta = 3$, $A_0 = 0 \text{ GeV}$, $\mu > 0$.

6.3 Verification of the Proposed Method in mSUGRA

To test the procedure proposed in section 6.2 we apply it to mSUGRA. We split our total trilepton acceptance into five channels using the same ratios as the trilepton analysis in chapter 4 for the two mass conditions. The background estimates from Table 4.10 are used to calculate limits on cross section times branching ratio according to section 5.3.1. The limits are compared to theory cross section obtained with PROSPINO 2.0[35] and PYTHIA 6.409[31] and the exclusion region in Fig. 6.2 is derived. Comparison to Fig. 5.30 shows that the proposed method is applicable.

⁶For the definition of the regions see section 5.2.1.

Figure 6.2: Exclusion region in mSUGRA obtained with the proposed model-independent approach. Comparison to Fig. 5.30 shows the applicability of the proposed method.

Chapter 7

Summary

Supersymmetry is a proposed symmetry that relates bosons and fermions and — if it is realized in nature — can answer some of the open questions of the Standard Model of Particle Physics. As supersymmetric particles have not yet been observed, supersymmetry has to be broken. mSUGRA is a model of supergravity where supersymmetry breaking is mediated by gravity. Due to its simplicity mSUGRA is widely used as a benchmark to evaluate searches for supersymmetry.

In this thesis a search for associated chargino-neutralino production in $\sqrt{s} = 1.96 \text{ TeV}$ center-of-mass energy $p\bar{p}$ collision at the Tevatron in 2 fb^{-1} of data from the Collider Detector at Fermilab (CDF II) is documented. The leptonic decay of chargino and neutralino is mostly via on- or off-shell sleptons or off-shell $W^{\pm*}/Z^{0*}$ bosons into leptons following

$$\tilde{\chi}_1^{\pm} \tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 l^{\pm} \nu_l \tilde{\chi}_1^0 l^{\mp}, \quad \text{where } l = e, \mu, \tau. \quad (7.1)$$

If R-parity is conserved, the lightest supersymmetric particle $\tilde{\chi}_1^0$ is stable and together with the weakly interacting neutrino provides missing transverse energy. The final state three leptons and missing transverse energy is often referred to as the “golden” trilepton channel as it is one of the most promising search channels for supersymmetry. In mSUGRA and similar models the lighter chargino, the two lightest neutralinos and the right-handed sleptons are, for most sets of parameters, considerably lighter than squarks and gluinos; additionally the trilepton final state has low Standard Model background at a hadron collider.

In this analysis electrons and muons are identified via their signals in the tracker, the calorimeter and the muon system. τ leptons can decay into an electron or a muon and be identified in the respective categories, but with branching ratio of approximately 50% τ leptons decay into a hadronic single-prong final state. To get acceptance to this decay we identify isolated tracks.

We expect $0.88 \pm 0.05(\text{stat}) \pm 0.13(\text{syst})$ events from background processes and observe 1 event in the analysis channels with three leptons; for an expectation of $5.5 \pm 0.7(\text{stat}) \pm 0.9(\text{syst})$ background events 6 events are observed in the channels with two leptons and one isolated track.

As this analysis is not able to find evidence for the production of supersymmetric chargino-neutralino pairs, 95% confidence level limits on the production cross section and branching ratio $\sigma \times \text{BR}$ are calculated. This analysis is the first chargino-neutralino search since LEP that is able to set a direct exclusion in mSUGRA. The exclusion is calculated as a function of the mSUGRA parameters m_0 and $m_{1/2}$.

A detailed study of the sensitivity of the analysis towards the full set of mSUGRA parameters is done and the important quantities for the ability of the analysis to set an exclusion are identified. It is shown that the ability to claim an exclusion mainly depends on the branching ratio $\text{BR}(\tilde{\chi}_2^0 \tilde{\chi}_1^\pm \rightarrow 3 \text{ leptons})$ and the average number of τ leptons in the final state. Based on these quantities a method for the generalization of the results of this analysis is developed. We split the analysis into channels for final states with 0, 1, 2 and 3 τ leptons and determine the acceptance as a function of masses individually. A method to obtain exclusions for other possible realizations of supersymmetry is provided.

Control Regions

The number of observed and expected events for dilepton and trilepton control regions is documented in Tables A.1 and A.2. The control regions are defined in Table 4.7.

Table A.1: Number of expected and observed events in the analysis channels for the trilepton control regions

Control Region	Channel	Predicted Background	Observed
Trilepton Control Regions			
!Zlo	$l_t l_t l_t$	6.3 ± 2.7	9
	$l_t l_t l_l$	2.2 ± 1.5	3
	$l_t l_l l_l$	1.4 ± 1.3	0
	$l_t l_t T$	88 ± 13	72
	$l_t l_l T$	34 ± 7	31
Zlo	$l_t l_t l_t$	10.8 ± 4.2	8
	$l_t l_t l_l$	4.9 ± 2.5	6
	$l_t l_l l_l$	2.8 ± 1.9	3
	$l_t l_t T$	223 ± 26	218
	$l_t l_l T$	195 ± 26	183
Zhi	$l_t l_t l_t$	2.7 ± 1.7	0
	$l_t l_t l_l$	1.7 ± 1.3	2
	$l_t l_l l_l$	1.6 ± 1.3	2
	$l_t l_t T$	26.8 ± 6.0	34
	$l_t l_l T$	27.7 ± 6.3	23

Table A.2: Number of expected and observed events in the analysis channels for the dilepton control regions

Control Region	Channel	Predicted Background	Observed

Appendix B

Limitations and Versions of PYTHIA and ISAJET

The combination of a ISAJET and PYTHIA, where a SUSY Les Houches Accord File is passed, is not considering mass widths for the calculation of branching ratios. This leads to problems in the region, where the transition from off-shell three-body decays (region A in Fig. B.2) to on-shell sequential two-body decay (region B in Fig. B.2) happens. In Fig. B.1 the branching ratio into three leptons is shown in this region. Due to the fact that no mass width is considered the decay changes from two-body to three-body once the three-body decay is kinematically allowed. This leads to the artificial behavior of the branching ratio for $94 \text{ GeV}/c^2 < m_0 < 97 \text{ GeV}/c^2$. Once the decay via on-shell particles is possible the branching ratio of the according off-shell decay is set to 0 and the branching ratio for the on-shell decay is calculated. As the mass of the slepton is approximately the mass of the chargino and neutralino, the available phase space for the decay products is small and the branching ratio drops. If mass widths would have been considered there would not be one point where the decay transition happens and a smooth curve for the branching ratio would be the case.

In Fig. B.2 a line shows the region where $m(\tilde{\chi}_1^\pm) = m(\tilde{\chi}_1^0) + m(W^\pm)$. It can be seen that around this line the branching ratio into three leptons is increasing. The reason can be seen in Fig. B.3. At $m_0 = 253 \text{ GeV}/c^2$ the decay $\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^\pm$ becomes kinematically allowed and the decay via off-shell $W^{\pm*}$ is turned off. As $m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_1^0) + m(W^\pm)$ the phase space for this decay is small and the branching ratio of the decay via an on-shell stau slepton increases until the phase space of the decay via on-shell W^\pm is big enough.

For this analysis different versions of PYTHIA and ISAJET have been used. The Monte Carlo Ntuples have been generated with PYTHIA 6.216 and ISAJET 7.51 while the calculation of the cross section and the branching ratio into three leptons was done with PYTHIA 6.409

Figure B.1: Branching ratio of chargino and neutralino into three leptons at the transition from off-shell three-body decay to on-shell sequential two-body decay. We don't differentiate between a decay via on-shell slepton, via off-shell slepton and via off-shell $W^{\pm*}$ or Z^{0*} boson for the branching ratio in this figure.

Figure B.2: Branching ratio of chargino and neutralino into three leptons

Figure B.3: Branching ratios for the chargino as a function of $m_{1/2}$ at benchmark point BP1 with $\mu > 0$

and ISAJET 7.75. In the CDF Monte Carlo production framework PYTHIA 6.216 was tuned to match the collected data, but no tune for more recent versions of PYTHIA is available. As newer ISAJET versions are not usable with PYTHIA 6.216, ISAJET 7.51 had to be used for the Monte Carlo production. It was decided to use the recent versions PYTHIA 6.409 and ISAJET 7.75, where no tune is needed.

Appendix C

Average Number of τ Leptons per Event

The trilepton analysis has channels with 3 genuine leptons and channels with 2 genuine leptons and one track. As the channels with a track have a worse signal to background ratio the sensitivity of the analysis is dependent on how many events fall into the two types of channels. The average number of τ leptons per event is a measure for this.

Figure C.1: Average number of τ leptons per event as a function of m_0 at benchmark point BP1 with $\mu > 0$

Figure C.2: Average number of τ leptons per event as a function of m_0 at benchmark point BP3 with $\mu < 0$

Figure C.8: Average number of τ leptons per event as a function of A_0 at benchmark point BP3 with $\mu < 0$

Appendix D

Monte Carlo Sample Generation for the Model-Independent Interpretation

In this section the generation of a Monte Carlo sample with 3 lepton final states including $i = 0, 1, 2, 3$ τ leptons as needed in section 6 is described. As the chargino can decay into no or one τ lepton and the neutralino into no or two τ leptons it can be concluded, that for final states with

- 0 τ leptons the chargino decayed into an electron or a muon and the neutralino decayed into electrons or muons,
- 1 τ lepton the chargino decayed into a τ lepton and the neutralino decayed into electrons or muons,
- 2 τ leptons the chargino decayed into an electron or a muon and the neutralino decayed into τ leptons,
- 3 τ leptons the chargino decayed into a τ lepton and the neutralino decayed into τ leptons.

In section 6 the description was limited to the cases where

1. $m(\tilde{\chi}_1^0) < m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0) < \text{mass of all other supersymmetric particles}$
2. $m(\tilde{\chi}_1^0) < m(\tilde{l}_R^\pm) < m(\tilde{\chi}_1^\pm) \approx m(\tilde{\chi}_2^0) < \text{mass of all other supersymmetric particles,}$
where \tilde{l}_R^\pm stands for the lighter selectron, smuon or stau.

As the mass parameters

1. chargino mass $m(\tilde{\chi}_1^\pm)$ and thus implicitly the mass of the neutralino,

2. $\Delta M_1 = m(\tilde{\chi}_1^\pm) - m(\tilde{l}_R^\pm)$,
3. $\Delta M_2 = m(\tilde{\chi}_1^\pm) - m(\tilde{\chi}_1^0)$.

are given the two case are equivalent to

1. $\Delta M_1 < 0$,
2. $\Delta M_1 > 0$.

It can be assumed that in case 1 the decay of the chargino and neutralino are as follows

$$\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 W^{\pm*} \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad \text{or} \quad (\text{D.1})$$

$$\tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^{\pm*} \nu_l \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (\text{D.2})$$

$$\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 Z^{0*} \rightarrow \tilde{\chi}_1^0 l^+ l^- \quad \text{or} \quad (\text{D.3})$$

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^{\pm*} l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^-. \quad (\text{D.4})$$

It is not important if the decay goes via an off-shell slepton or an off-shell $W^{\pm*}$ or Z^{0*} boson; in both cases a three-body decay is taking place. In case 2 the decay is mostly

$$\tilde{\chi}_1^\pm \rightarrow \tilde{l}_R^\pm \nu_l \rightarrow \tilde{\chi}_1^0 l^\pm \nu_l \quad (\text{D.5})$$

$$\tilde{\chi}_2^0 \rightarrow \tilde{l}_R^\pm l^\mp \rightarrow \tilde{\chi}_1^0 l^+ l^-, \quad (\text{D.6})$$

where the sleptons are on shell. For most models it is sufficient to assume 100% branching ratio via on-shell slepton.

For every set of mass parameters four Monte Carlo samples with 0, 1, 2, 3 τ leptons in the final state are produced. We set the masses of $\tilde{\chi}_1^0$, $\tilde{\chi}_2^0$, $\tilde{\chi}_1^\pm$, \tilde{e}_R^\pm , $\tilde{\mu}_R^\pm$ and $\tilde{\tau}_1^\pm$ to

$$m(\tilde{\chi}_1^0) = m(\tilde{\chi}_1^\pm) - \Delta M_2, \quad (\text{D.7})$$

$$m(\tilde{\chi}_2^0) = m(\tilde{\chi}_1^\pm), \quad (\text{D.8})$$

$$m(\tilde{e}_R^\pm) = m(\tilde{\mu}_R^\pm) = m(\tilde{\tau}_1^\pm) = m(\tilde{\chi}_1^\pm) - \Delta M_1. \quad (\text{D.9})$$

The masses of all other supersymmetric particles are set to high values. For the decay of the sleptons we set all branching ratios to 0 except $\tilde{l}^\pm \rightarrow \tilde{\chi}_1^0 l^\pm$ to which the branching ratio 100% is assigned. For the chargino and the neutralino we set the branching ratios of all decay channels except the ones mentioned later to 0.

Branching Ratios for the Case $\Delta M_1 > 0$

For the sample with $i = 0$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 e^\pm \nu_e) = 50\% \quad (\text{D.10})$$

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 \mu^\pm \nu_\mu) = 50\% \quad (\text{D.11})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 e^+ e^-) = 50\% \quad (\text{D.12})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \mu^+ \mu^-) = 50\% . \quad (\text{D.13})$$

For the sample with $i = 1$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 \tau^\pm \nu_\tau) = 100\% \quad (\text{D.14})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 e^+ e^-) = 50\% \quad (\text{D.15})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \mu^+ \mu^-) = 50\% . \quad (\text{D.16})$$

For the sample with $i = 2$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 e^\pm \nu_e) = 50\% \quad (\text{D.17})$$

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 \mu^\pm \nu_\mu) = 50\% \quad (\text{D.18})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \tau^+ \tau^-) = 100\% . \quad (\text{D.19})$$

For the sample with $i = 3$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 \tau^\pm \nu_\tau) = 100\% \quad (\text{D.20})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 \tau^+ \tau^-) = 100\% . \quad (\text{D.21})$$

Branching Ratios for the Case $\Delta M_1 < 0$

For the sample with $i = 0$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{e}_R^\pm \nu_e) = 50\% \quad (\text{D.22})$$

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\mu}_R^\pm \nu_\mu) = 50\% \quad (\text{D.23})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{e}_R^\pm e^\mp) = 50\% \quad (\text{D.24})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\mu}_R^\pm \mu^\mp) = 50\% . \quad (\text{D.25})$$

For the sample with $i = 1$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\tau}_1^\pm \nu_\tau) = 100\% \quad (\text{D.26})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{e}_R^\pm e^\mp) = 50\% \quad (\text{D.27})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\mu}_R^\pm \mu^\mp) = 50\%. \quad (\text{D.28})$$

For the sample with $i = 2$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{e}_R^\pm \nu_e) = 50\% \quad (\text{D.29})$$

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\mu}_R^\pm \nu_\mu) = 50\% \quad (\text{D.30})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\tau}_1^\pm \tau^\mp) = 100\%. \quad (\text{D.31})$$

For the sample with $i = 3$ we set the branching ratios

$$\text{BR}(\tilde{\chi}_1^\pm \rightarrow \tilde{\tau}_1^\pm \nu_\tau) = 100\% \quad (\text{D.32})$$

$$\text{BR}(\tilde{\chi}_2^0 \rightarrow \tilde{\tau}_1^\pm \tau^\mp) = 100\%. \quad (\text{D.33})$$

For the case that $\Delta M_1 < 0$ and a significant branching ratio of the decays $\tilde{\chi}_2^0 \rightarrow \tilde{\chi}_1^0 l^+ l^-$ or $\tilde{\chi}_1^\pm \rightarrow \tilde{\chi}_1^0 l^+ l^-$, it is possible to use 8 samples, where four samples are produced for $\tilde{\chi}_1^\pm$, ΔM_1 , ΔM_2 and four samples where ΔM_1 is set to a positive value. The total acceptance for case i is then the acceptance obtained from both samples weighted by the appropriate branching ratio

$$A_{\text{total}} = \text{BR}(\text{off-shell decay}) \times A_{\text{off-shell}} + \text{BR}(\text{on-shell decay}) \times A_{\text{on-shell}}. \quad (\text{D.34})$$

Vita

Julian Glatzer was born in Eberbach, Germany on October 18, 1984. He graduated from Nicolaus-Kistner-Gymnasium Mosbach with the German high school diploma “Abitur” in 2004. He studied at the University of Würzburg with major physics from 2004 to 2007 and with major mathematics from 2005 to 2007. He completed his undergraduate studies in physics with “Vordiplom” in 2006 and in mathematics with “Vordiplom” in 2007. In 2007 he joined the graduate program of Rutgers University and started work with Prof. Sunil Somalwar in the CDF Collaboration.
